Abstract

The aim of this study is to combine petrophysical and geochemical data in order to reconstruct the migration history and pathways of mixed microbial-thermogenic gases drilled in the Nile Delta fan, offshore Egypt. While general interest lies in understanding migration routes, rates and mechanisms special attention is dedicated to understanding (1) the origin of gas in both reservoir and non-reservoir units using chemical and isotopic fingerprints and (2) whether a free gas phase supports relatively rapid leakage via bulk flow in non-reservoir units, both above and below commercial accumulations.

The Pliocene section in this study is a classic slope environment comprising channels, mud-rich turbidites, mass transport complexes and hemipelagites. Data from seismic and drilled wells suggest that the channel and levee reservoirs are rarely full to spill, implying either a lack of charge and/or a balance between charge and leakage rates which precludes complete filling of the structures. The provided data set enables a quantitative assessment of gas distribution and its genetic fingerprint in the context of both stratigraphic position and lithology. Data is reported from 25 wells, each provided with a conventional wireline log suite and some with borehole images and high-quality core images. Gas concentration data, plus compositional and isotope data are available from isotubes and headspace gas for both reservoir and non-reservoir units. Small-to-medium scale linear and non-linear depth shifts between different techniques (core recovery, core logging, wireline logging) in conjunction with scale and resolution issues demanded logical/stochastic depth synchronisation as well as harmonisation of signal resolution (typically upscaling). Accordingly, great care was taken to depth-match core, log and gas data.

In general, there is evidence of leaking thermogenic and partly biodegraded gas from the reservoirs under investigation, while some microbial methane appears to be retained in the cap rock. Careful assessment of the maturity of the thermogenic gas charge suggests that in a given structure, maturities are similar throughout the sampled section of underseal, reservoir and top seal. Furthermore, compositional temperature stratification suggests a balance between influx of fresh gas and microbial metabolism rates, supporting the concept of a dynamic charge-leak scenario that is sustaining hydrocarbon fermenting microbial communities in the deep biosphere. It was found that microbial recycling of hydrocarbons at depth enables the identification of diffusive gas mixing pathways in the combined analysis of methane and ethane compositional and isotopic data. The proposed diffusion pattern supports the idea of a widely present coupling between both methanogenic and biodegrading microbial communities that exhibit strong carbon isotopic disbalances at gas-water contacts (GWC) where nutrient supply is in favour of

the biodegrading metabolism. Although the hypothesis of coupled diffusive/microbial gas overprints complies with (1) various literature reports that microbial attack on free gas phases is hindered by restricted physical access and (2) segregative isotope fractionation as a consequence of differences in methane and ethane diffusivity, it is conditional to the nature of gas mixing patterns along borehole trajectories in the context of lithology and pore fluid saturations.

Undoubtedly, the ubiquitous presence of microbial gas has consequences for vertical net leakage. As classic empirical wireline models for hydrocarbon saturation (*i.e.* free gas phase volumetrics) are not suited for clay-dominated cap rock sections, an alternative approach presented in this study is based on total gas (TG) modelling from nuclear logs and its solubility in the formation brine. The calibrated saturation model is scale-independent and implies that free gas occurs in most of the clay-dominated non-reservoir sections. However, model resolution is not sufficient to capture the suspected filamentary network of free gas phase within the mudrock pore space that enables relatively rapid leakage via Darcy flow.

In an unique attempt to validate manual and thereby subjective lithofacies allocations to core images a subset of rock sample properties such as grain size fractions and porosity were successfully modelled using quantitative core image properties. However, model validity appears to be restricted to clay-rich lithofacies due to both absence of calibration data for sands and occurrence of abnormally dark sandstone units. Further, an artificial neural network (ANN) was trained to propagate the calibrated core facies along the entire wireline logged borehole section to set the lithological context for a detailed fluid flow analysis. Reproducibility of input (core) facies by output (wireline) facies is similar to the reproducibility by fellow geoscientists but could be significantly improved to 60-80% reliability by reduction of facies types.

The study shows that a combination of geochemical data with lithological and petrophysical information generates detailed insights into rates, mechanisms, and pathways of two phase flow through the deep biosphere of gas-charged basins. Vertical, geologically rapid flow through mud-rich sequences is a viable migration route for gas if the influence of cap rock bypass systems (permeable faults, sandstone intrusions, mud volcanoes etc.) is restricted. It was found that an adequate quantification of both thermogenic gas fraction and diffusive gas mixing fingerprints is crucial to identify stratigraphic intervals that are not dominated by advective leakage through the pore space and are consequently bypassed.

Acknowledgements

Firstly I would like to express my gratitude to Professor Andy Aplin for his guidance and encouragements during the wonderful time that I have spent in Newcastle. Special thanks are dedicated to Dr. Kuncho Kurtev and Michael Drews for sharing their combined brain-power in handling the countless geostatistical issues that arose from data integration, and for their friendship over all these years.

It has been a great pleasure working with qualified researchers from various UK Universities under the umbrella of the *Caprocks Project*. Dr. Aggeliki Georgiopoulou and Professor Joe Cartwright provided invaluable insights into the world of seismic interpretation and their ideas had a great influence on the outcome of my project. Further, I would like to thank Professor Gary Couples, Dr. Jingsheng Ma, Dr. Tiago Alves, Phil Green, Dr. Xiuwen Mo, Maggie White, and Dr. Mohamed Rouainia for their kind support. Deep gratitiude is expressed to Dr. Tatiana Goldberg for her independent peer reviews and constructive comments. Also, I would like to thank my examiners Professor Thomas Wagner and Dr. James Illife for their recommendations to clarify critical aspects of my work.

This Ph.D. project has been funded by the *Caprocks Project* consortium. Appreciation is expressed to BP for supplying samples and data, and to its management for permission of publication. Special thanks are addressed to Tim Dodd for sharing his knowledge and experience about the Nile Delta petroleum system and for his patience in explaining the details of applied petroleum engineering.

Chapter 1 Introduction

The aim of this integrated study is to determine the nature and magnitude of natural gas leakage through the pore network of fine-grained clastic sediments.

Leakage is understood as the physical transport of petroleum across a reservoir seal, or beyond the spill point of a filled trap, resulting in petroleum loss. A more general term for the movement of petroleum in the sub-surface is migration, which circumscribes both leakage and charge of accumulations through various processes. Attributes of both lacking charge and/or presence of leakage are present in the Pliocene gas reservoirs of the western Nile Delta case study since these are underfilled with column heights that vary with their stratigraphic position.

A combined analysis of rock samples, core images, wireline log signals, borehole gas data, and seismic cross sections clearly enables a comprehensive and thus promising approach to define the migration/leakage processes and mechanisms involved in the case study (Fig. 1–1). To date, the integration of these multi-scale data has been one of the fundamental problems in the analysis of basinwide fluid flow (Schlömer & Krooss 1997). The scientific drive of this project is therefore accompanied by major economic implications beyond the area under investigation.

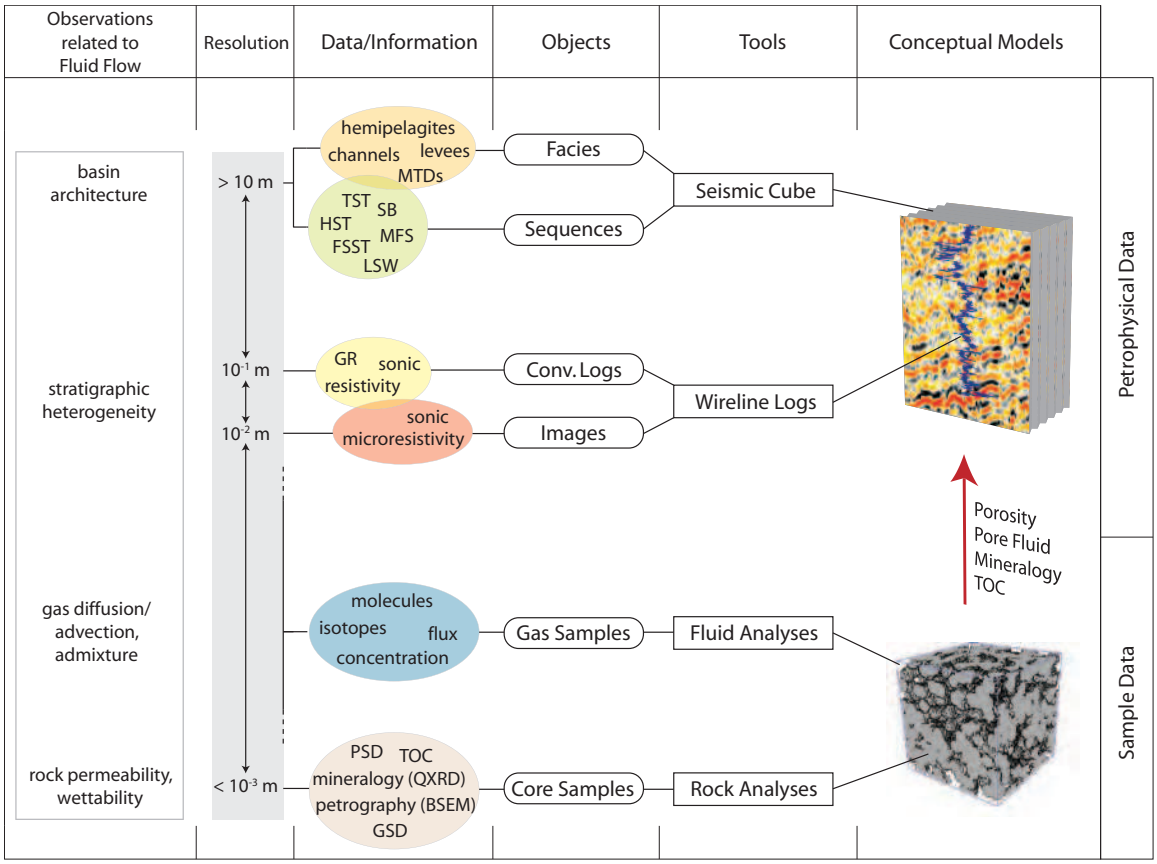

Figure 1–1 Field and sample data overview: Relationships linking the physical and spatial characterisation of seal sections with the tracking of fluid flow/gas leakage within these poorly permeable rock units; both on the micro (sample) and macro (basin) scale. See '*List of abbreviations and acronyms*'.

1.1 The Western Nile Delta Fan

The study area is the deltaic depositional system of the Western Nile Delta fan, offshore Egypt, which has existed since the Messinian salinity crisis had subsided 5.3 Ma ago (Garfunkel 1998 & 2004).

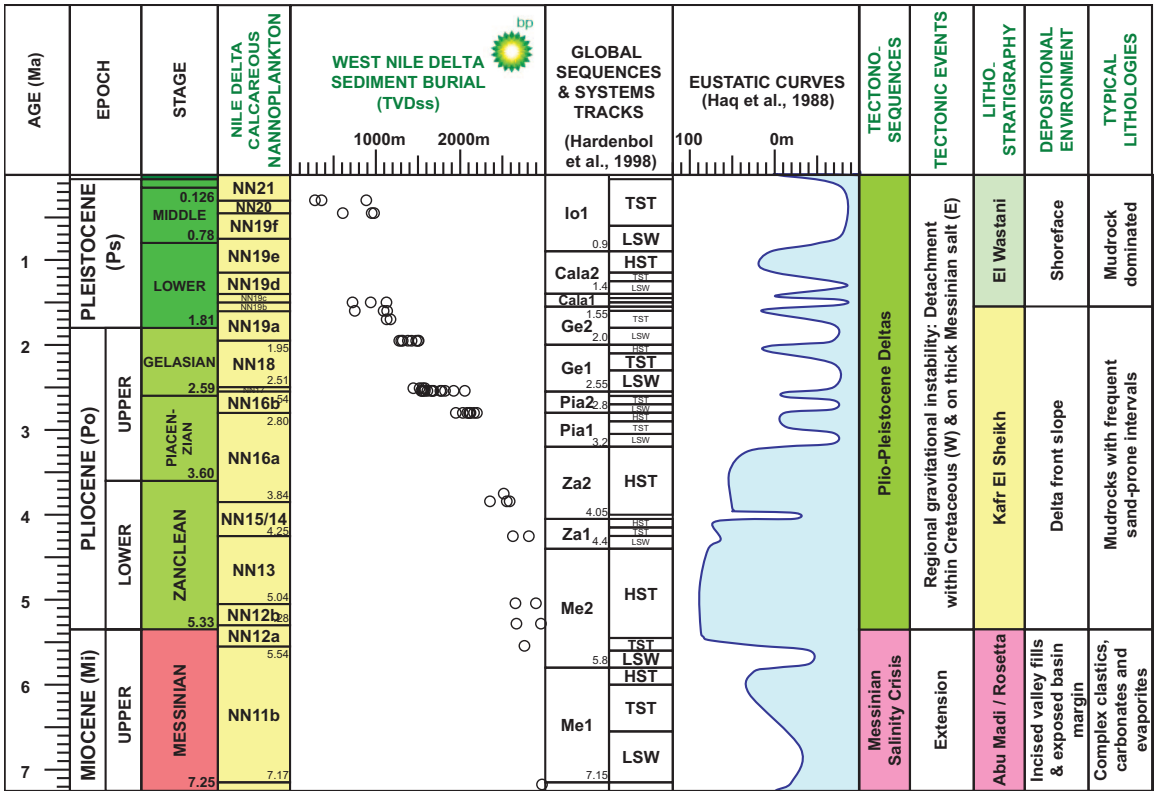

Figure 1–2 BP stratigraphic framework and nomenclature for the Nile Delta area.

The Pliocene and Pleistocene deltaic sediments were deposited at an average rate of ~480 m/Ma (see Fig. 1–2 and Vandré *et al.* 2007) and – in analogy to the present day seafloor map (Fig. 1–3) – comprise facies that would be expected in a classic slope environment: potential reservoir deposits such as channels and turbidites, and the mud-rich cap rock units from widespread background sedimentation of hemipelagic fall-out. In addition, some units are affected by faulting and sliding (Mascle *et al.* 2001, Garziglia *et al.* 2008). The presence of mud volcanoes and pockmarks implies an active degassing of the petroleum system below, which is to over 98% dominated by methane. This work focuses on an area where most of the boreholes are located (red frame in Fig. 1–3).

The Pliocene amplitude maps of the focus area (Fig. 1–4) demonstrate the widespread distribution of the mud-rich cap rocks of the Upper Pliocene – especially in the central area. It will be shown that some of the analysed cap rock core samples could retain hydrocarbon column heights exceeding 1000m – given that advective flow is restrained by insufficient gas phase saturations within the mudstone pore space. However, data

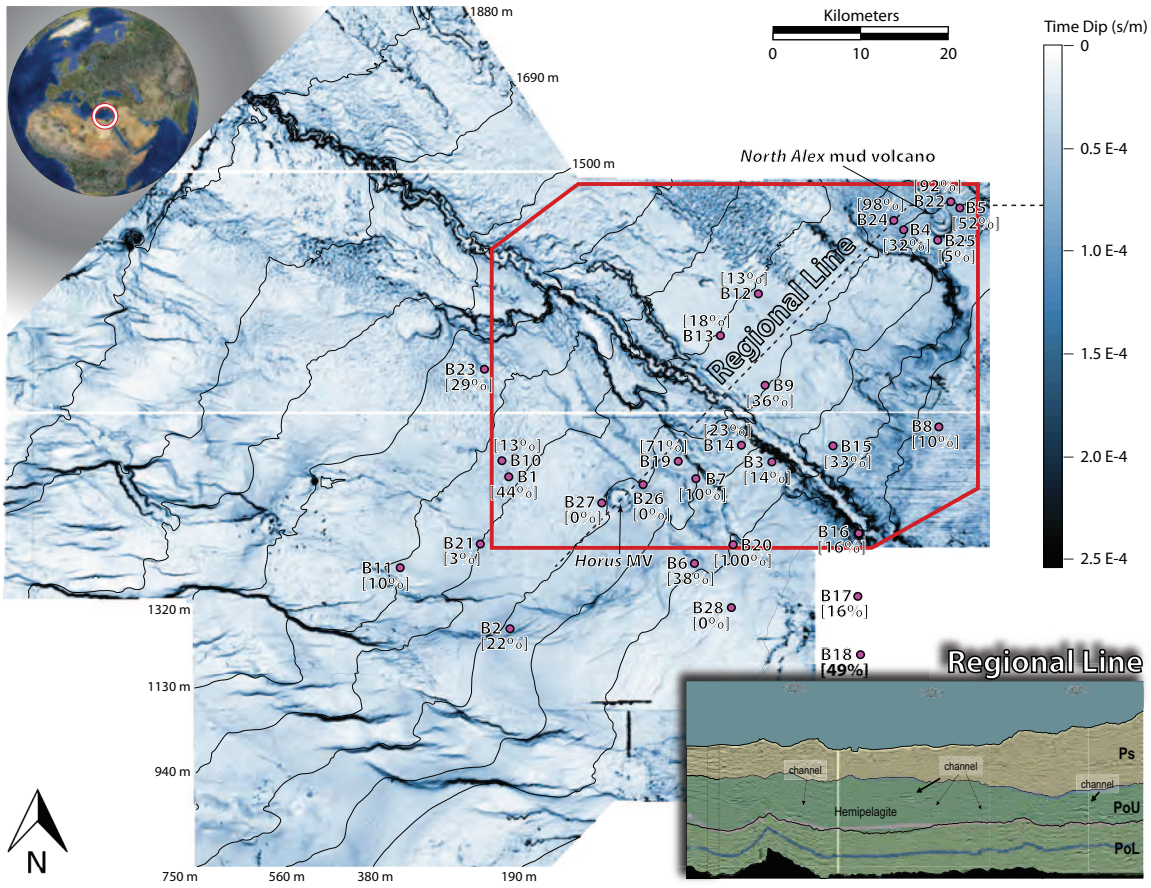

Figure 1–3 Seafloor dip-map of the western Nile Delta fan with borehole locations (B1-B28) and focus area (red frame). Average data abundance per well with respect to B20 is given in brackets (see caption of Fig. 1–6). The regional seismic line outlines the ~3km thick post-Messinian succession of Lower and Upper Pliocene (light/dark green) and the Pleistocene sediment cover (yellow).

from seismic and drilled wells suggest that the underlying channel, levee, and lobe reservoirs are rarely full to spill (*cf*. BP Egypt). Basically, there are two possible explanations for these observations: either (a) lack of charge or (b) the column heights are controlled by a dynamic charge/leakage system with relative migration rates that preclude complete filling of the structures.

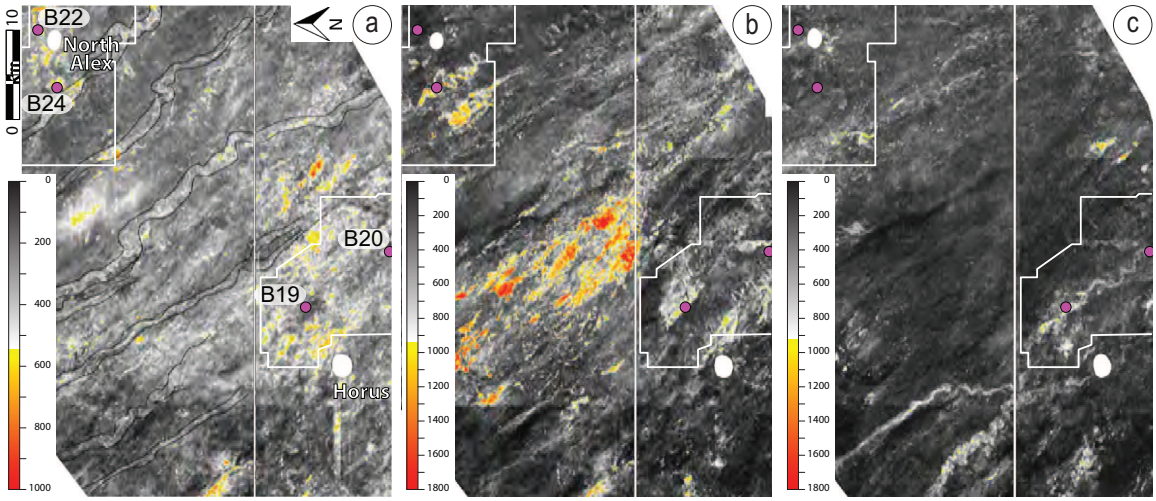

Figure 1–4 Seismic amplitude maps (~80 ms thick) of (a) Lower Pliocene, (b) Lower-to-Upper Pliocene transition, and (c) Upper Pliocene hemipelagite cap rock of the focus area. Locations of Horus and North Alex case studies, priority wells, and mud volcanoes are marked. Legends show magnitude of RMS amplitudes (ms).

This study is focused on understanding the migration routes, rates and mechanisms that are involved in the case study. In principle, gas migration may take place along one or both of two general routes: (a) high permeability, seismic-scale bypass systems including injected sands and sands juxtaposed at *e.g.* levee-levee connections ("multi-storey migration"; Cartwright *et al.* 2007), and/or (b) predominantly vertical flow through the pore network of mud-rich sediment sequences (Schowalter 1979). In this relatively shallow region low pore fluid overpressures preclude micro-fracturing and potential large-scale conduits are readily identified on seismic as gas-bearing anomalies. However, their role as migration pathways for thermogenic gas (that arrives from an unspecified sub-Messinian source rock) is always uncertain due to the ubiquitous generation of microbial gas in this area. Mixing of these two genetic gas types and potential biodegradation precludes a purely seismic approach on unravelling the movement of gas within the western Nile Delta fan. Alternatively, this migration study is based on the interpretation of fluid geochemical fingerprints in the context of borehole lithological profiles and pore fluid volumetrics. A detailed outline of the data and workflow involved is given in Chapter 1.2.

1.2 Data Resources and Case Studies

A quantitative assessment of gas distribution and its genetic fingerprint in the context of both stratigraphic position and lithology requires a comprehensive data set. The *Caprocks Project* group provided access to a seismic cube of the study area that is penetrated by 25 boreholes, each provided with a conventional wireline log suite and some with bore-

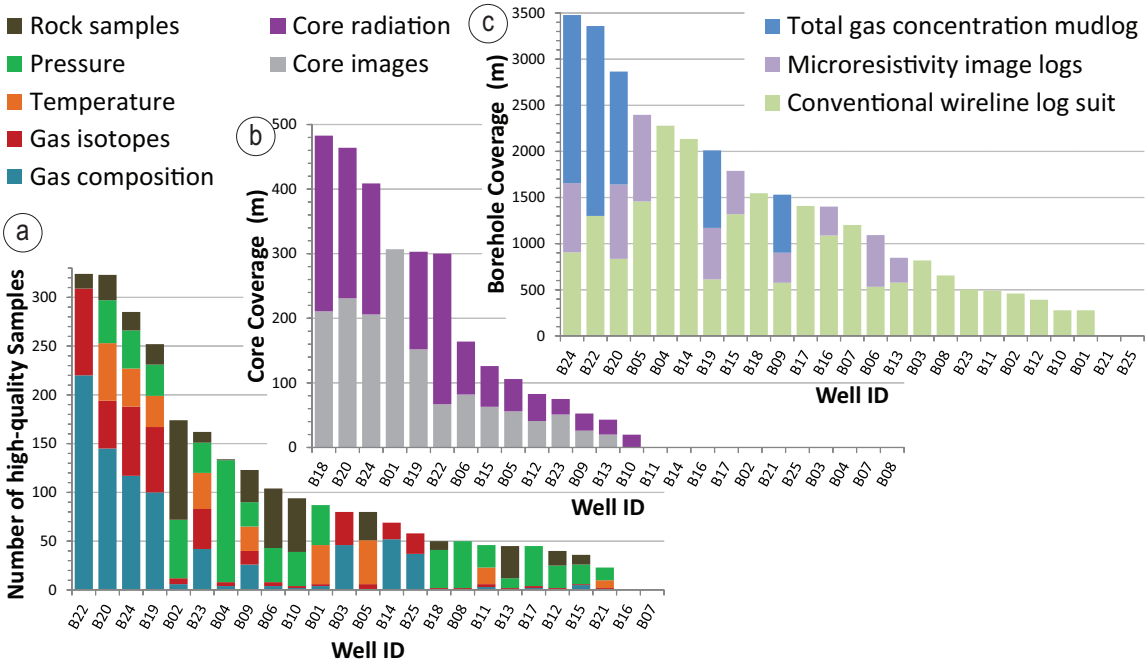

Figure 1–5 Detailed distribution of data availability for the provided boreholes. The database may be split into (a) isolated samples from rock coring, RFT downhole measurements, and wellsite fluid sampling, (b) core logs, and (c) borehole logs.

hole images and high-quality core images. For calibration of these petrophysical signals a mudrock database with various measurements of more than 300 samples from the study area was provided; 92 rock sample analyses with focus on fine-grained sealing units were conducted by the author. Gas concentration data, plus compositional and isotope data are available from various wellsite and downhole measurements for both reservoir and non-reservoir units. Data abundance and coverage are illustrated in Figure 1–5.

Four wells that meet a sufficient data coverage for the required measurement depth synchronisation were selected for detailed analysis (Fig. 1–6). The geographic positions of these priority wells generated two case studies that are named after their closest mud volcanoes (MV): Horus and North Alex (see wells and white outlines in Fig. 1–4a).

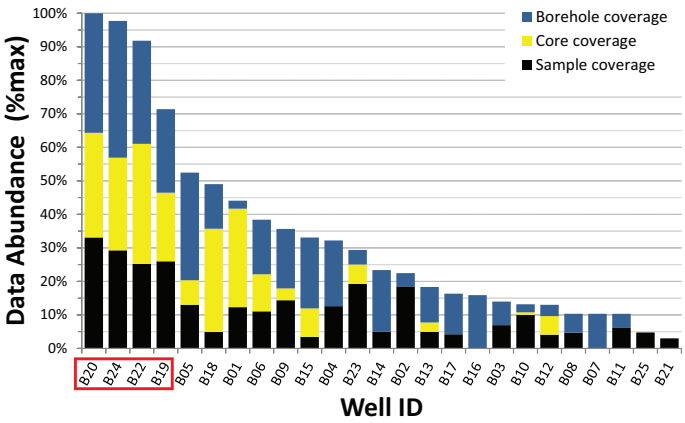

Figure 1–6 Average data abundance per well relative to the well with the highest coverage (B20≡100%). The four wells with the best data coverage were chosen as priority wells (red frame: B19, B20, B22, B24).

The Horus case study Wells B19 and B20 penetrate the same channel/levee complex (Fig. 1–7), but B20 does not contain a commercial gas column height (CH_{max}~25m) as opposed to B19 (CH_{max}~230m) which is located at the structural crest (Fig. 1–8).

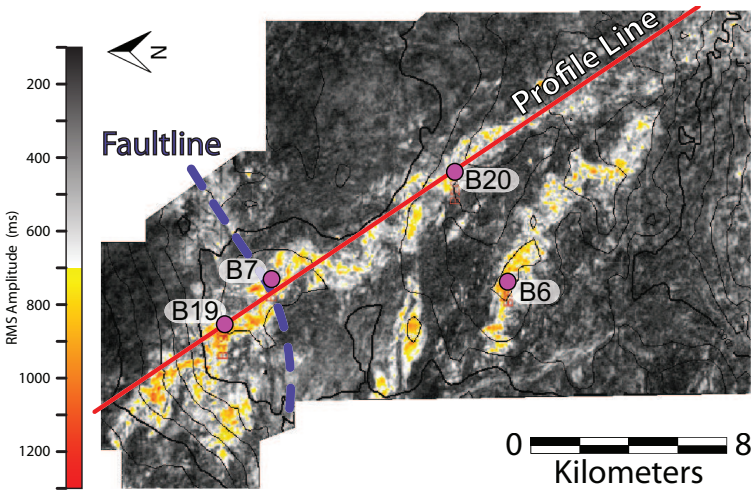

Figure 1–7 Trap configuration at Wells B19 and B20 in the Horus case study. Both wells penetrate the same channel that is compartmentalised into separate reservoirs of differing quality. See geographical overview map in Figure 1–4.

Drill-stem tests (DST) revealed that there is very poor pressure communication between the two wells, which leads to the conclusion that there is at least one sealing fault responsible for reservoir compartmentalisation. The ultimate top seal is dominated by levee and mass transport deposits (Fig. 1–8). Questions that arise from this scenario are whether gas from Well B19 has intruded the cap rock, whether B20 has lost its gas through the seal or has never received charge, and which of the two scenarios is feeding the present-day pockmark above the faultline in Figure 1–8.

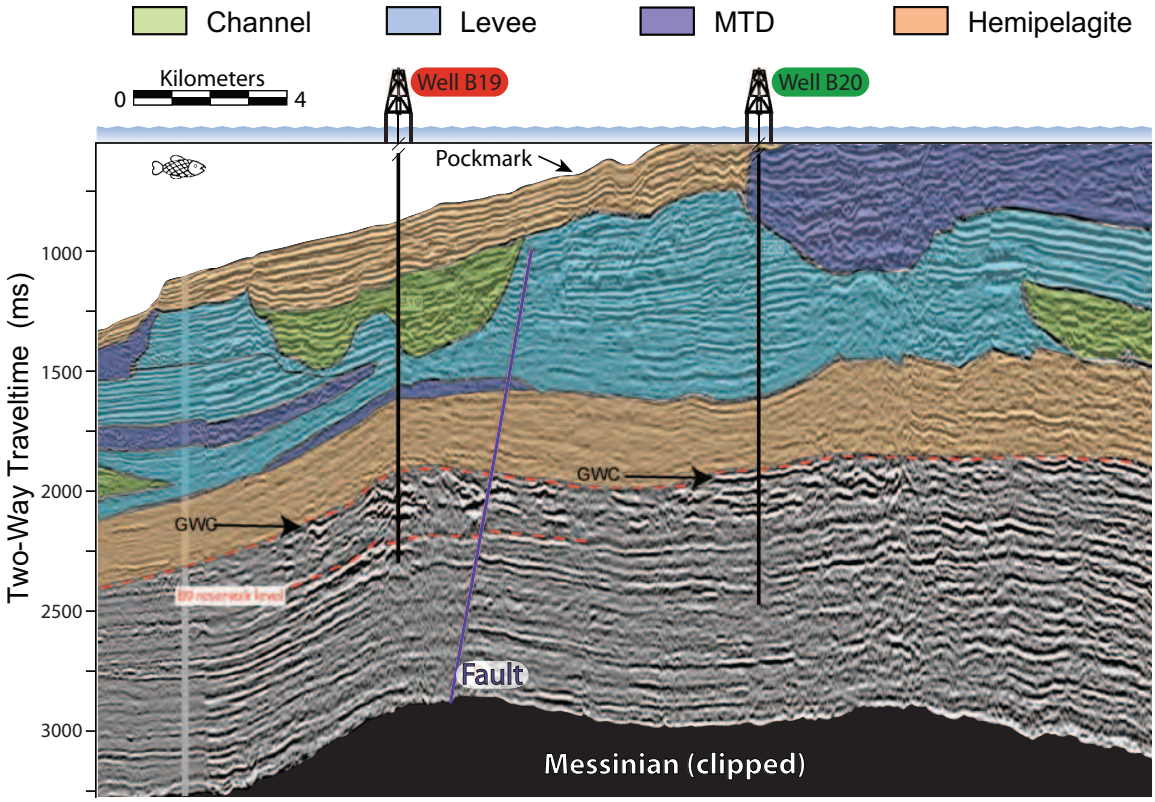

Figure 1–8 Down-slope seismic profile along the B19/B20 channel. Profile line in Fig. 1–7. Gas-water contacts (GWC) marked by dashed red lines. Messinian seismic is not granted for publication. Seismic interpretation courtesy of A. Georgiopoulou.

The North Alex case study Well B22 penetrates a levee reservoir that is connected to its adjacent channel (CH_{max}~100m; at location of Well B5 in Fig. 1–9) while B24 penetrates a channel reservoir (CH_{max}~280m) that is likewise in lateral communication with a gas bearing levee (Fig. 1–9). The cap rock along B22 is dominated by levee deposits whereas the B24 reservoir is situated at the base of a complex channel system that may

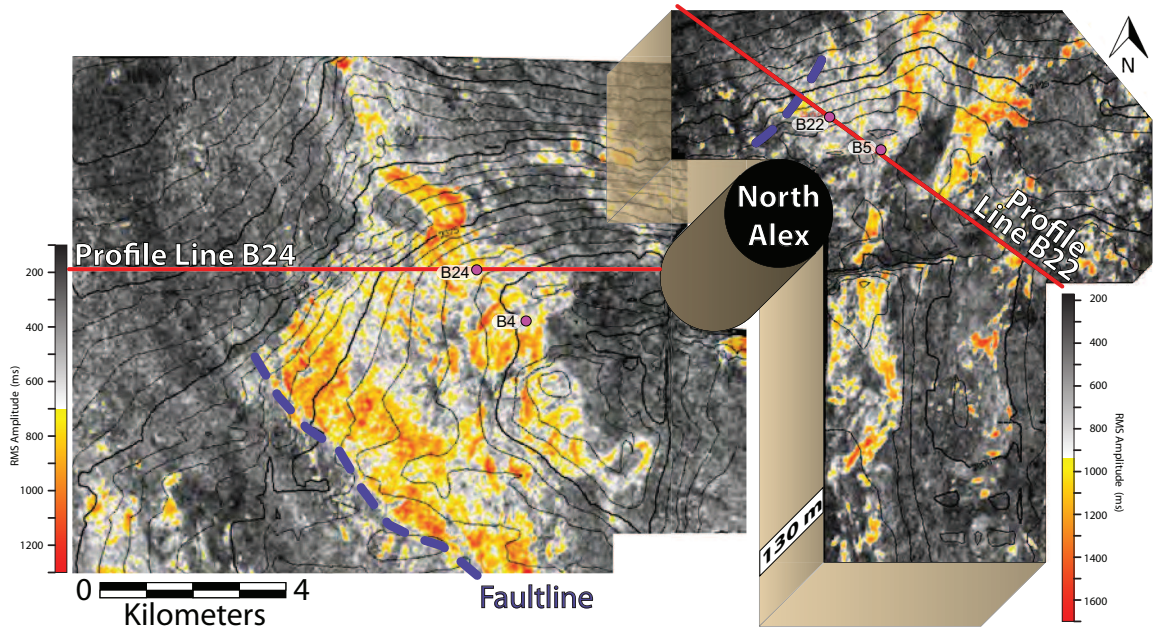

Figure 1–9 Trap configuration at Wells B22 and B24 in the North Alex case study. The two wells penetrate different reservoirs in the vicinity of the North Alex mud volcano. See geographical overview map in Figure 1–4.

pose an elevated leakage risk (Figs. 1–10a,b). Although Wells B22 and B24 feed on different reservoirs at different stratigraphic intervals both are (1) marginally confined by a normal fault and (2) located in the close vicinity of the same major mud volcano (MV) called North Alex.

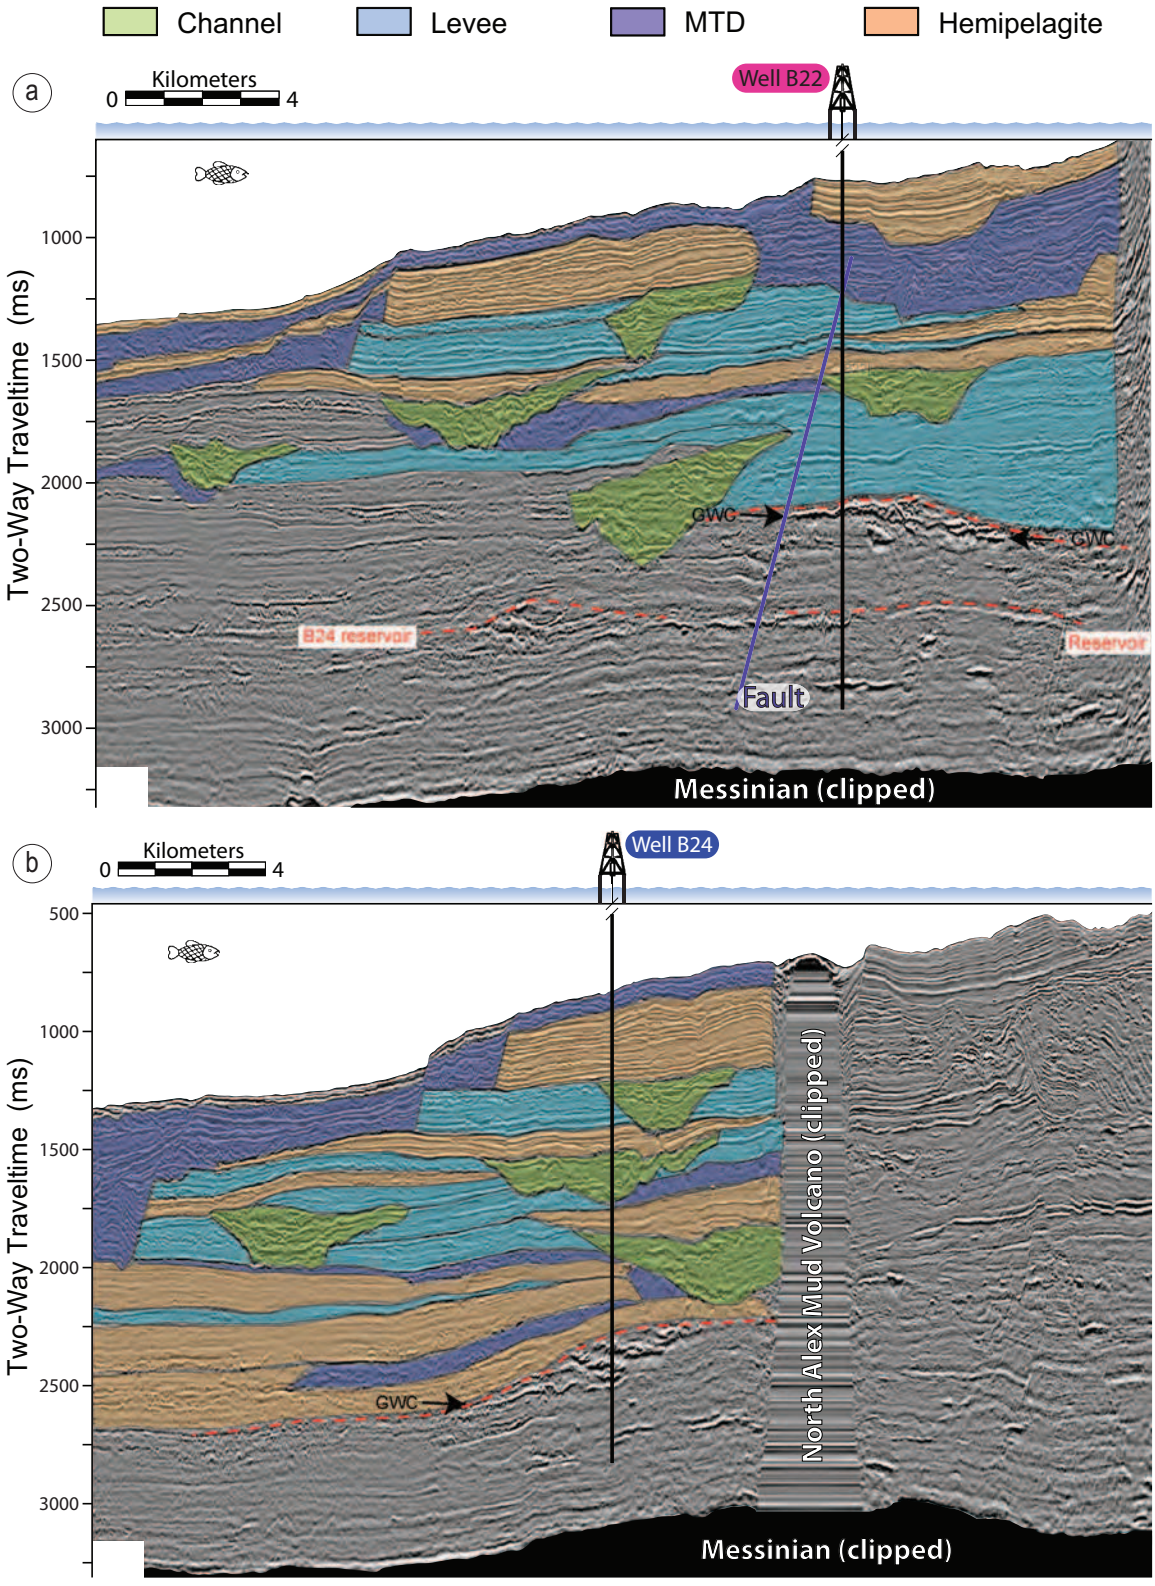

Figure 1–10 Down-slope seismic profile through the borehole section of (a) Well B22 and (b) Well B24. Profile lines in Fig. 1–9. Gas-water contacts (GWC) marked by dashed red lines. Messinian and mud volcano seismic are not granted for publication. Seismic interpretation courtesy of A. Georgiopoulou.

Prominent cap rock bypass systems The mapping of strong seismic amplitude contrasts across the marginal faults – particularly in the case of B24 (Fig. 1–9) – implies that they are laterally impermeable. However, there is a risk that sub-vertical gas migration along their down-dip plane plays a major role in the charge/leakage behaviour of these two reservoirs. In fact, the fault-related occurrence of MV in the Nile Delta area (*e.g.* Dupré *et al.* 2010) indicates that at least some faults have significant fluid conductive properties. Loncke *et al.* (2004) suspected that fluid migration along reactivated basement faults initiated the generation of Western Nile Delta MVs such as North Alex and Horus (Fig. 1–2), and Garziglia *et al.* (2008) speculate that fault-related leakage may widely affect the tectonic activity in this area. Lipid biomarker studies of carbonate crusts that were precipitated by shallow anaerobic oxidation of methane (AOM) imply a stable and presumably steady seepage activity at a central Nile Delta pockmark during the last 5 Ma (Gontharet *et al.* 2009), *i.e.* the system has already received a mixed thermogenic/microbial hydrocarbon charge at the sediment interface during the early Pliocene. Furthermore, an eastern Nile Delta study from Mastalerz *et al.* (2007) suggests an episodic, pulse-like contribution to MV eruption activity on the basis of differing sea water column hydrocarbon concentrations that were measured during two subsequent seafloor expeditions (NAUTINIL Sep-Oct 2003: rel. lower conc.; MIMES Jun-Jul 2004: rel. higher conc.). Consultation of World Stress Map data implies that a contemporary and drilling-related earthquake might be responsible for this observation (16/06/2004 at 1.6 km burial depth within the study area; Heidbach *et al.* 2008). These observations suggest the mutual influence of fault-bound gas migration and fault activity as an extention to the aforementionend ideas of Garziglia *et al.* (2008). Mud volcanoes in the Levantine Basin, offshore Israel, were also reported to bypass the Plio-/Pleistocene stratigraphy (Netzeband *et al.* 2006), *i.e.* the deep-rooted nature of mud volcanoes seems to be a common feature of the eastern Mediterranian. This explains why fluid emissions are dominated by (deep) thermogenic gas that reflects source rock maturities which are significantly increasing towards the east (Dupré *et al.* 2007 & 2010 – and references therein).

Dupré *et al.* (2010) report that MV feeder channels in the Nile Delta area usually do not exceed a few metres in diameter although stratigraphic disruptions may exceed a radius of 1km (*e.g.* Fig. 1–10; clipped data). In addition to these seismic observations (1) the presence of peripheral seeps allocated to subsidiary conduits of the North Alex MV (Dupré *et al.* 2007) and (2) the general presence of a subordinate microbial gas fraction in coexistence with isotopic traces of deep anaerobic wet gas biodegradation in shallow MV sediment samples (Mastalerz *et al.* 2007 & 2009) give rise to the question whether such large-scale cap rock-bypass systems (CBS) are capable of tapping Plio-/Pleistocene gas

reservoirs within a radius of 2.3-5.1 km – such as in the case of Wells B22 and B24, respectively.

1.3 Challenges of Wellsite Data Integration

The basic prerequisite for a successful integration of a broad variety of field and borehole-related measurements is inevitably the coherence of depth. In other words, cause-and-effect relations may only reasonably be inferred from data that are confirmed to be measured at the same reference depth. The provision of such depth coherency is utterly critical in small-scale heterogeneous strata such as laminated reservoir cap rock sections. In terms of conventional borehole data acquisition there are basically three different depth referencing techniques that are not easily brought into line.

First, the driller's depth relates to all downhole measurements taken during the initial drilling of a new well. It is the coring reference, *i.e.* the depth at which the provided rock samples have been recovered from. This type of depth is referenced to the length of the steel string and relates to the rate of penetration (Fig. 1–11). Inevitably, there is hazard of incoherency by steel string expansion and replacements on drilling progress. These process-related depth uncertainties are accompanied by non-linear distortion of the recovered core that may be ascribed to issues such as core loss (*e.g.* by unconsolidated rock and cuttings wash-out between cored intervals) as well as unloading, clay swelling and desiccation shrinking (Anderson 1975). Core gamma ray (COGR) and microresistivity borehole image (OBMI) scans will give a critical contribution to core depth matching in order to establish depth coherency (see Appendix A for details).

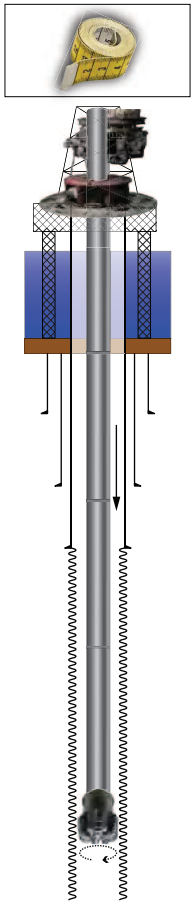

Figure 1–11 Driller's depth scheme

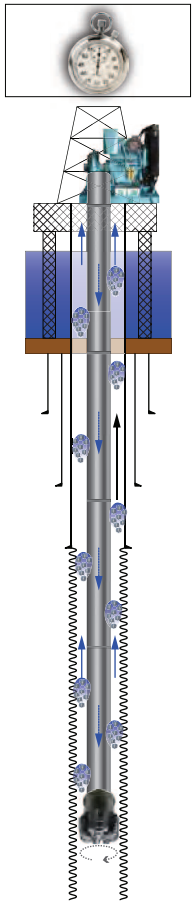

Figure 1–12 Mudlog depth scheme

Second, probably the least accurate depth measurement taken is the mudlog depth. It is estimated from the driller's depth and borehole fluid circulation rate (Fig. 1–12), relating to all the measurements involving the borehole outflow while drilling. The inconsistent mixture of borehole fluid (mostly oil-based in the case study), natural gas, saline formation water and drill cuttings is permanently being scanned for basic E&P and wellsite safety issues directly at the well head. Most valuable data referring to the mudlog depth

concern gas chemical and isotopic compositions obtained from Isotube and FID measurements (see Chapter 3.1). In addition to inconsistencies caused by complex multi-phase flow regimes, the potential contribution of drilling side-effects such as 'swap gas' and 'connection gas' (both phenomena related to drill string withdrawal) and circulation fluid disbalances account for non-linearities in depth matching of mudlog data (Whittaker 1985, T. Dodd personal communication). Unfortunately, the most frequent disturbances in the gas sample-to-depth relation occur within the cored interval where sampling frequencies are commonly higher than elsewhere. In consideration of these various interferences it was decided to undertake a stochastic procedure of matching the measured TG log to a wireline log gas model (see Appendix A for details). Fluid samples taken directly downhole may serve as a quality control for shifting of the mudlog depth.

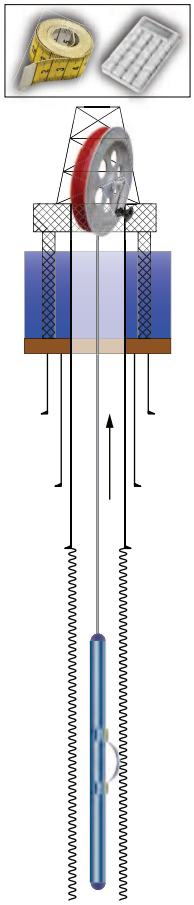

Figure 1–13 Logger's depth scheme

Third, the logger's depth refers to the complete suit of wireline log signal profiles acquired along the borehole. Being the common reference for all post-drilling wellsite activities as well as traveltime-to-depth conversions of seismic surveys, a major effort is undertaken by the logging contractor to ensure that this master reference depth reflects the "true" depth along the borehole as accurately as possible. Common corrections – for example – involve issues of acceleration caused by tool clogging and systematic errors like wireline expansion (Fig. 1–13; Serra & Serra 2003). In addition to conventional wireline log responses such as resistivity and gamma ray, borehole image scans and sparse downhole fluid samples (RFT/MDT) will prove critical to confirm the correction of driller's and mudlog depth to the common logger's depth.

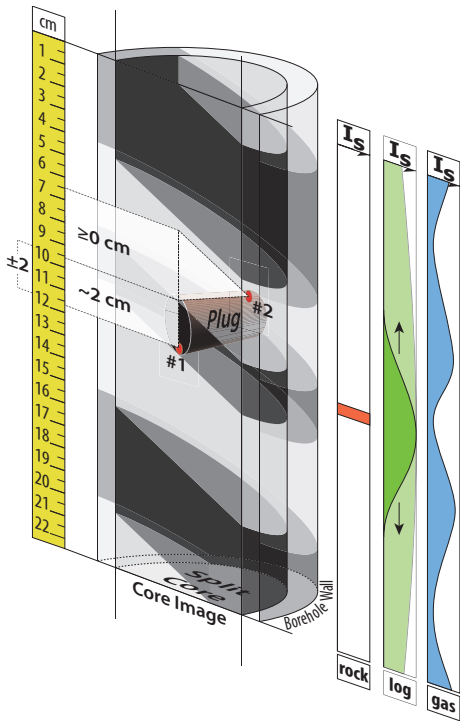

Figure 1–14 Uncertainties in the exact provenance of the sub-sample for laboratory rock analysis poses a severe risk for the plug-to-core depth integrity (see text). Scale, resolution, and signal intensities (I_S) vary between different techniques.

Careful depth-matching of core, log and gas data creates the starting situation for the integrated analysis of this multi-scale and multi-resolution data set. However, even after a successful depth synchronisation there remain severe discrepancies concerning scale and resolution between the applied measurement techniques (Fig. 1–14). For example, the vari-

ous destructive laboratory experiments that are conducted at the rock sample resolution (~5mm) require multiple sub-sampling of a heterogeneous core plug (*e.g.* at locations #1 and #2 in Figure 1–14). Integration of measured parameters such as grain and pore sizes would be highly error-prone in this case simply because the heterogeneity of clay-bearing rocks is commonly high at the sampled resolution and reproduction of identical sub-samples for multi-probing is elusive. Further – in conjunction with depth synchronisation – techniques such as rock sampling, core/wireline logging and gas sampling require a harmonisation of signal resolution prior to integration (Fig. 1–14; Appendices A and B). Usually the highest resolution will be upscaled in order to meet the lowest resolution to compare with (Zinszner & Pellerin 2007). Depth synchronisation, signal harmonisation, and the involved limitations due to resolution discrepancies are largely described in the respective appendices of this thesis.

As mentioned earlier, potential migration routes and seal risk assessments – particularly in the petroleum industry – are traditionally evaluated and validated through the analysis of seismic surveys (*e.g.* Cartwright *et al.* 2007). However, gas seepage at low concentrations is not resolved on seismic, and *in situ* production of gas by microbial activity in the deep biosphere may lead to the misinterpretation of seismic-scale gas pockets as the local ponding along an active migration pathway. Alternatively, this study suggests that careful investigation of gas volumetrics and geochemical fingerprints in both seismic and lithological context yields new insights into basin-scale migration at an elevated resolution.

The approach is implemented by consultation of gas geochemical evidence from subsurface fluid samples (Part I), borehole lithological context (Part II), and partition of water and hydrocarbon gas in the pore space (Part III). A synthesis of the derived borehole profiles from the first three parts of this thesis will be translated into schematic gas migration scenarios through the local and regional basin architecture in Part IV (Fig. 1–15).

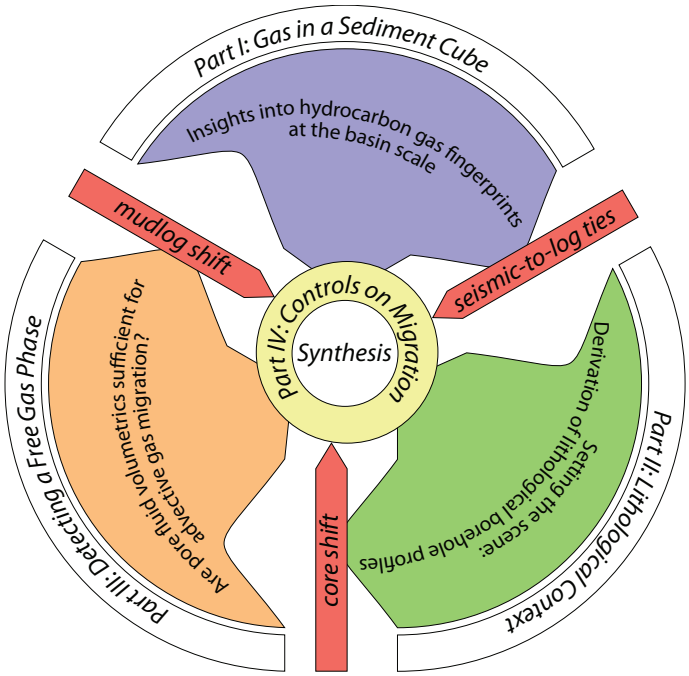

Figure 1–15 Schematic workflow for the integration of available data sets for a better understanding of the gas migration history within the case study.

Part I – Gas in a Sediment Cube

The name "Gas in a Sediment Cube" was chosen because this first part focuses on analysing the combined wellsite gas data sets from the Western Nile Delta subsurface to determine (and quantify) the most prominent effects on gas geochemistry, involving state-of-the-art concepts of hydrocarbon gas genesis and its geochemical evolution upon secondary alteration processes.

Identifying the relative impacts of both genetic (primary) and post-genetic (secondary) imprints on recovered gas samples allows their translation into time-dependent proxies such as degree of genetic mixing, thermal maturity of the source rock during gas expulsion, and progress of microbial alteration.

A detailed well-by-well discussion of migration mechanisms and pathways will conclude this work in Part IV.

Chapter 2 Geochemical context

The geochemical study of natural gases, oils, and their organic precursors is of interest due to the fact that hydrocarbon gases are omnipresent primary products of organic maturation at all stages of burial. They range from early microbial/diagenetic methane, formed in shallow anoxic sediments down to depth exceeding 1000 meters, through to thermogenic gases associated with oil generation, or higher temperature methane produced during metamorphism of organic matter (OM; *e.g.* Clayton 1991, Norville & Dawe 2007). Hence, molecular and isotopic gas signatures potentially unravel the genetic and post-genetic hydrocarbon history and behaviour in sedimentary basins, *e.g.* source type and maturity, gas mixing, as well as migration effects and leakage (Clayton 1991, Prinzhofer *et al.* 2000a & 2000b).

Tracking this genetic code utilizes data only of two different kinds: the molecular proportions of each species (*e.g.* CH_4, C_2H_6, etc.) and the stable isotope ratios of each chemical element (*e.g.* ^{12}C *vs*. ^{13}C, ^{1}H *vs*. ^{2}H or D) involved in each molecular species. In particular, the carbon isotopic composition of methane and, somewhat more recently, the hydrogen isotopic composition have been found useful for recognition of the origin of a gas. Both parameters are primarily dependent on the type and maturity of the source (Schoell 1983), as well as secondary fractionation and gas mixing effects. However, hydrogen isotopes need to be handled with great care due to the acknowledged potential of hydrogen to be exchanged with other species, *e.g.* formation water and meteoric aquifer water (Schimmelmann *et al.* 1999).

As isotopic differences are small, changes are usually highlighted by referring sample isotopic ratios to a common standard. This normalization is expressed by the δ notation (Tissot & Welte 1984), *e.g.* for $\delta^{13}C$:

$$\delta^{13}C\ [‰] = [(^{13}C/^{12}C)_{sample} / (^{13}C/^{12}C)_{PDB}] - 1 \cdot 1000 \qquad \textbf{\textit{(2a)}}$$

In other words, the higher the δ value, the relatively more of the heavier isotope counterpart comprise the sample. The common standard for $\delta^{13}C$ is PDB, whereas δD values refer to the standard mean ocean water (SMOW; Craig 1961). Measured δ values are given in per mil and are usually negative for organic carbon and hydrogen, which is basically due to (1) the kinetically favoured incorporation of the lighter isotopes during photosynthesis prior to burial and (2) thermal alteration of the gas organic precursor (*e.g.* $\delta^{13}C_{org}$ = -30 to -20 ‰). Hence, the inorganic standards are relatively enriched in ^{13}C respectively D (Tissot & Welte 1984, Whiticar 1996).

The distribution of different genetic or primary gas mixtures – *e.g.* along vertical bore-

hole sections – will help to track reservoir leakage and potential migration pathways although concurrent secondary overprints may partially disguise the original gas signature. Primary hydrocarbon generation is discussed in Chapter 2.1, followed by a section on microbial gas generation and secondary recycling (Chapter 2.2), and an overview on abiogenic secondary overprints that may occur during hydrocarbon migration through the pore space (Chapter 2.3).

2.1 Primary origins of hydrocarbon species

Natural gas comprises naturally occurring hydrocarbons, mainly methane (C1) with variable amounts of wet gas components (C2+), as well as commonly small amounts of other compounds such as N_2, H_2S, CO_2, He and H_2O (Tissot & Welte 1984). The distinction and quantification of the two fundamental genetic gas types, thermogenic and microbial, is important since it helps to identify and characterise the source during an early exploration stage, can suggest the presence and quality of liquid hydrocarbons in the reservoir, and may indicate whether previously reservoired gas has entered the seal (Leith *et al.* 1993, Abrakasa 2009).

Thermal Cracking The distribution of oil and gas in sedimentary basins is commonly explained by the hypothesis of thermal cracking at elevated temperatures: gas/oil ratios and gas ratios (dryness = C1/ΣC1-5) tend to increase with organic source maturity and depth due to the disintegration of free radicals in the order kerogen → oil → wet gas → dry gas by a process called beta-elimination (Mango 2001). Prinzhofer *et al.* (2000b) list the following three possible origins for thermogenic gases generated in the source rock

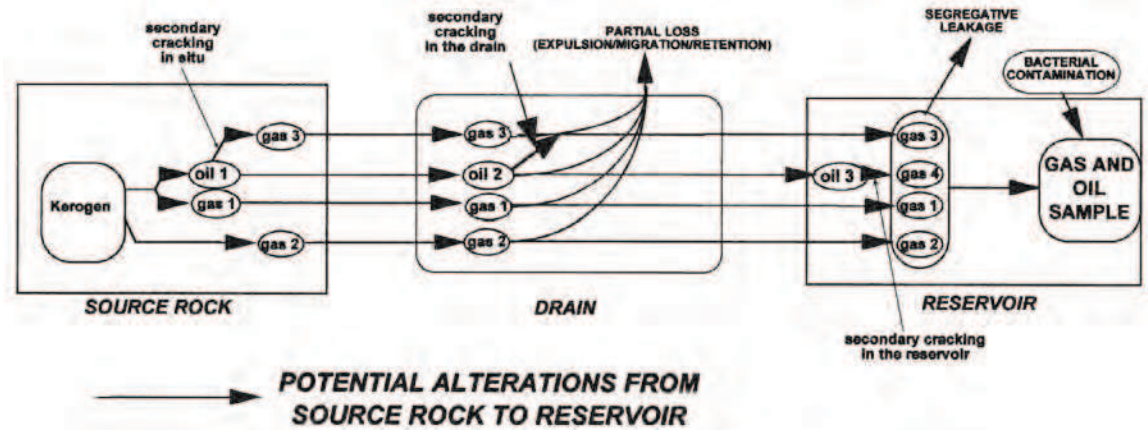

Figure 2–1 General scheme of hydrocarbon gas history from its genesis to its sampling (from Prinzhofer *et al.* 2000b). In the source rock, three different gas steps of formation may be defined: gas generation associated with the oil, late gas generation from the mature kerogen, and secondary cracking of the oil remaining in the source rock. In the reservoir, after expulsion and migration, two other possible gas inputs may be distinguished: secondary cracking of the reservoired oils and bacterial contamination. Hydrocarbon segregation due to transport may occur in the source rocks, in carrier beds, and within the reservoir.

(Fig. 2–1): (1) kerogen-derived gas during oil genesis (primary cracking), (2) late gas generation from the kerogen (primary cracking), and (3) gas generated by the thermal degradation of the source-bound, generally heavy oil (secondary cracking). Additionally, a fourth hydrocarbon gas fraction may derive from the reservoir-bound thermal decomposition of the oil (secondary cracking).

However, there is no chemical evidence to support the idea of naturally cracking wet gas to dry gas (> 80% methane) over geological time at typical subsurface temperatures without catalytic assistance (Mango *et al.* 1994, van Aarssen *et al.* 1999). Mechanisms that are discussed to contribute to the controversial large methane proportion of natural gases include gas fractionation due to expulsion (Inan 2000) and migration (Price & Schoell 1995, Schoell 1995), and gas catalysis due to traces of reduced transition metals (*e.g.* Mango 2000 & 2001). As a rule of thumb, thermogenic gas contains at least 2% of higher gaseous alkanes C2+ (Fuex 1977, Rice & Claypool 1981, James 1983, Mattavelli *et al.* 1983, Schoell 1983, England 1990, Coleman 1992, Schoell *et al.* 1993).

Apart from the debatable molecular genesis of natural gas, its isotopic fingerprint appears to be well understood on the basis of a kinetic isotope effect (KIE): The cracking of an isotopically lighter molecule is energetically favoured over its heavier counterpart due to differences in covalent bond strength (*e.g.* Stahl 1974, Tang *et al.* 2000). Moreover, the lighter the molecule, the lighter it is isotopically, with all hydrocarbons being depleted in heavier isotopes relative to the source kerogen. Consequently, as the latter passively enriches in the heavier isotope with reaction progress, *i.e.* with increasing maturity, this isotopic shift in the source is inherited by the subsequently produced hydrocarbons (Fig. 2–2; Sackett 1978, Clayton 1991, Andresen *et al.* 1995, Whiticar 1996, Prinzhofer *et al.* 2000b, Tang *et al.* 2005).

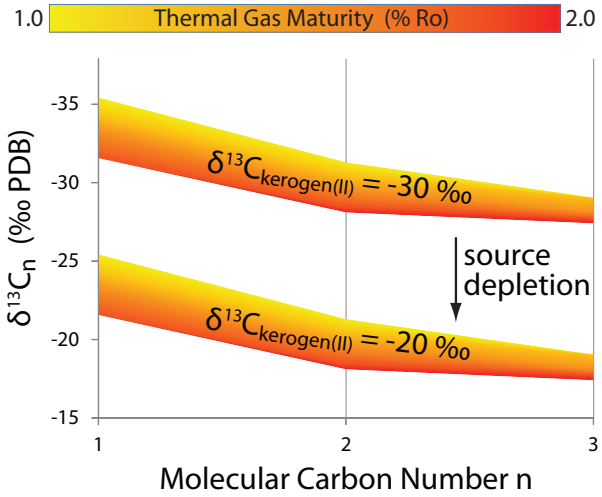

Figure 2–2 Gradual depletion of ^{13}C in the source kerogen amplifies the thermal maturity effect on carbon isotope ratios of expelled hydrocarbons (after the maturity model of Berner & Faber (1996) for type-II kerogens).

Microbial Cracking The natural gas formed in sediments during diagenesis is termed biogenic or microbial gas. It is a waste product of methane producing archaea or methanogens during the decomposition of organic matter in poorly drained swamps, bays, anoxic freshwater lake bottoms, glacial drift, and marine sediments beneath the zone of active sulfate reduction at some tens of meters depth down to temperatures exceeding

75°C (Rice & Claypool 1981 – and references therein). A secondary source of microbial methane relates to wet gas and oil biodegradation at the base of hydrocarbon accumulations (Scott *et al.* 1994, Jones *et al.* 2008). Accumulations of microbial gas are found in recent to Cretaceous sediments with extensive turbidite, delta and/or coastal plain facies that have had a low-temperature history (Clayton 1992, Norville & Dawe 2007).

The distribution of microbial gas in the subsurface can shed some light on its migration history only if the stratigraphic intervals that host the major production sites are known. That is why habitat and metabolism of both methanogens and biodegrading microbes as an important part of the diverse microbial environments of the deep biosphere are summarised in the following section.

2.2 Microbial activity in the deep biosphere

Over the last decades, a range of archaeal and bacterial species has been recovered from various depths via fluid and core samples, both cultivated and uncultivated (Dong & Yu 2007, Fredrickson & Balkwill 2006 – and references therein). All these microorganisms were found to metabolise organic matter (OM) by a series of coupled oxidation-reduction reactions.

In marine environments, the two general processes for metabolising OM are (1) respiration (both aerobic and anaerobic) which utilizes inorganic compounds as electron acceptors, and (2) fermentation in which electron transfer occurs within or between organic compounds (Rice & Claypool 1981, Tissot & Welte 1984, Hunt 1996, Whiticar *et al.* 1986). Selective advantage is given to species capable of catalysing the various processes most efficiently, *i.e.* the nature of the microbial population of a given habitat is determined by (1) respective energy yield of metabolic reactions and (2) environmental constraints. Accordingly, the ecological succession of metabolic processes varies with time and burial depth, with less efficient organisms at greater depth (Rice & Claypool 1981; Fig. 2–3). At this point consideration should be given to the fact that only trace concentrations of H_2S were sampled from the Plio-/Pliostocene Nile Delta at temperatures well below 90°C, *i.e.* most of the available gas data has been sampled within the methanogen window (see Fig. 2–3).

In general, the deep biosphere is considered to harbour mainly fermentative and methanogenic anaerobes in an aqueous environment that provides dissolution and transport of organic and inorganic nutrients for biosynthesis (Röling *et al.* 2003). Overall activity of such buried microbial communities can be constrained by the rate of nutrient diffusion (Tyler *et al.* 1994) – particularly in stratigraphy with limited pore water saturation (Kieft

et al. 1993) – as well as by intolerable salinity and temperature conditions (Grassia *et al.* 1996, Tardy-Jacquenod *et al.* 1996).

If adequate environmental conditions are met the metabolic respiration of inherent microbial communities is dependent on the availability of electron donors (reductants or "energy") and electron acceptors (oxidants or "electron sinks"). Electron donors are usually provided via microbial fermentation and abiotic decomposition of sedimentary organic matter (Carothers & Kharaka 1978, Routh *et al.* 2001), mineral hydrolysis (*e.g.* Bennett *et al.* 2001), and/or the influx of dissolved hydrocarbons (Tyler *et al.* 1994). Reduced inorganic cations from mineral diagenesis (especially S, Fe, Mn), CO_2, and – in the case of oil biodegradation – possibly certain types of organic compounds serve as oxidants (Röling *et al.* 2003).

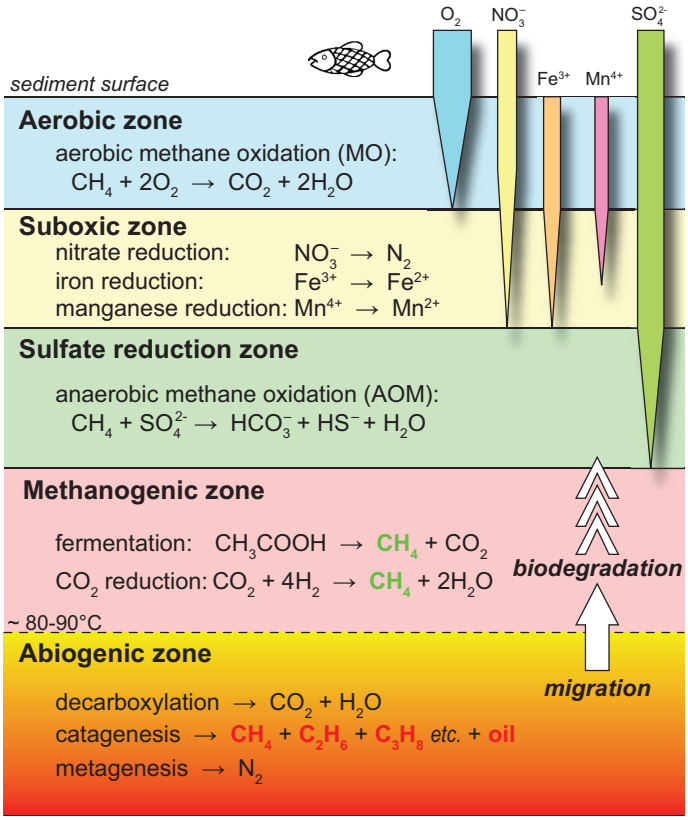

Figure 2–3 Diagrammatic cross section of organic-rich, open-marine environment showing succession of microbial ecosystems that lead to methane generation and recycling (reproduced from Clayton 2010, with supplements from Valentine 2002).

However, frequent discoveries of new prokaryote species support the impression that as yet, only little is known about the ecology and evolution of microbes in the deep biosphere.

Temperature implications Temperature optima can be relatively narrow depending on the respective microbial species (Zeikus & Wolfe 1972). Optimum growth conditions for methanogens have repeatedly been reported between about 30°C and 50°C (*e.g.* Zeikus & Winfrey 1976, Wellsbury *et al.* 1997) while those for biodegrading microbes may range to as much as 70°C (Grassia *et al.* 1996). An empirical termination threshold at 80–90°C for fermentative micro-organisms in petroleum accumulations is widely acknowledged (Head *et al.* 2003). This temperature threshold indicates a fatal rate disequilibrium between an already slow anaerobic biosynthesis (Jones *et al.* 2008) and increasingly fast thermal decomposition of life sustaining organic compounds beyond the tolerated temperatures (Bernhardt *et al.* 1984, Phipps *et al.* 1991).

Consequently, pasteurisation of uplifted reservoirs indicates that HC fermenting or biodegrading microbes evolve during burial rather than having colonised upon hydrodynamic injection (Wilhelms *et al.* 2001a). Methanogens are likewise considered original habitants due to pore throat and thus transport restrictions in mudstones (Momper 1978, Chapelle & Lovley 1990, Fredrickson *et al.* 1995, Rebata-Landa & Santamarina 2006).

Physical nutrient access Multiple evidence suggests that anaerobic biodegraders are physically related to the rock matrix rather than colonise the pore space as plankton. For instance, Crump *et al.* (1998) argue that particle- or matrix-attached microbes have the benefit of direct access to sedimentary OM and its fermentation products. This would explain why inherent microbial communities did not get flushed out of the system during burial (Wilhelms *et al.* 2001a) unless they possess over flagellar filaments (*e.g.* Malapaka & Tripp 2006).

Microbial access requires dissolved (hydrocarbon) nutrients that may thereby be exposed to diffusive isotope fractionation effects (Bouchard *et al.* 2008a & 2008b). By analogy, ebullitive gas releases have been reported to inhibit aerobic microbial oxidation in shallow zones of low hydrocarbon saturation (Chanton *et al.* 1992, Grant & Whiticar 2002).

Further, microbes may have access to solid nutrients by direct contact, via organic electron shuttles (Nevin & Lovley 2002; Fig. 2–4), or via a coupled degradation-dissolution process induced by extracellular enzymes in biofilms (Crump *et al.* 1998). MacLean *et al.* (2008) suggested that organic polymers in biofilms are capable of creating chemical microenvironments by modulating diffusion processes.

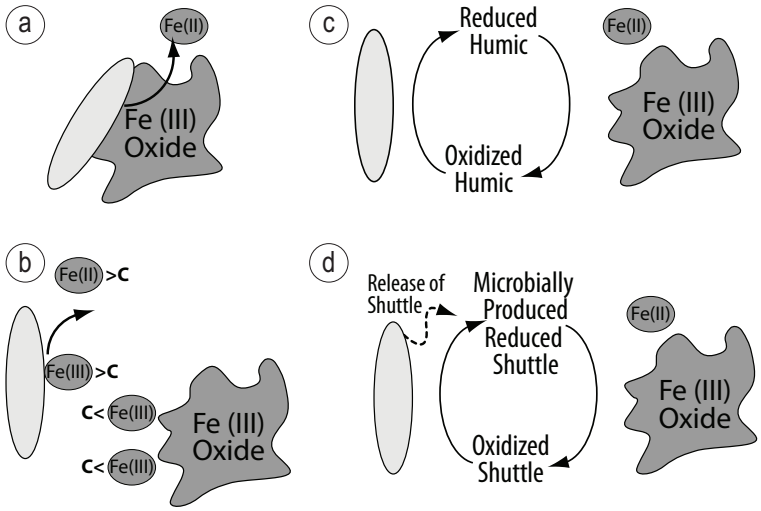

Figure 2–4 (a) Reduction of Fe^{3+} oxide via direct contact between Fe^{3+}-reducing organism and Fe^{3+} oxide. (b) Fe^{3+} reduction in the presence of soluble Fe^{3+}. (c) Fe^{3+} reduction via electron shuttling with soluble humic substances. (d) Fe^{3+} reduction via a bacterially produced electron shuttle (reproduced from Nevin & Lovley 2002).

Biodegradation Methane (C1) oxidation yields the highest energetic benefit of all hydrocarbons species (Whiticar 1994). In the deep biosphere, anaerobic oxidation of methane (AOM) has been allocated to a consortium of archea that live in a syntrophic relationship to sulfate-reducing bacteria (SRB; Hinrichs *et al.* 1999, Boetius *et al.* 2000).

A minor contribution to the microbial diversity of the sulfate-reduction zone (see Fig. 2–3) is provided by sub-terminal hydrocarbon degradation of C2 and branched species such as iso-butane (iC4; Kniemeyer *et al.* 2007).

In contrast, microbial attack of saturated hydrocarbons that bear non-terminal C-atoms such as C3 and normal-butane (nC4) is a widely reported phenomenon in petroleum accumulations beyond the sulfate-reduction zone (*e.g.* Kinnaman *et al.* 2007) and may have a syntrophic connection to the microbial synthesis of short-chained hydrocarbons (Jones *et al.* 2008). Since there is no evidence of AOM that is decoupled from SRB the microbial consumption of hydrocarbons in sulfate-free anoxic environments lead to a selective reduction of oil and wet gas components with the result of both compositional and carbon isotopic depletion – an effect that mimics the KIE at increasing thermogenic source rock maturity for non-methane hydrocarbons.

Methanogenesis However, also C1 chemical and isotopic compositions of the degrading thermogenic gas are altered by admixture in the zone of active methanogenesis (see Fig. 2–3). Here, microbial gas consists predominantly of methane, which is enriched in the light isotopes ^{1}H and ^{12}C (δD = -530 – -170 ‰; $\delta^{13}C1$ = -110 – -55 ‰) owing to kinetic isotope fractionation by strictly anaerobic methanogens (Whiticar 1999). The methane carbon isotopic composition is primarily affected by $\delta^{13}C$ of the original substrate and possible admixture of isotopically heavier thermogenic gas (Rice & Claypool 1981). Laboratory determination of natural microbial ethane concentrations range from 3 ppm to 0.9 % with $\delta^{13}C2$ ~ -55 ‰ (Davis & Squires 1954, Oremland *et al.* 1988, Lückge *et al.* 2002).

Although traces of higher hydrocarbons (wet gas) were successfully produced in laboratory fermentation experiments, microbial-dominated natural gas accumulations usually exceed these experimental wet gas concentrations (Rice & Claypool 1981 – and references therein). Analysis of gas samples from the Deep Sea Drilling Project (DSDP) indicate that gas of predominantly microbial origin contains higher hydrocarbons in amounts which are directly proportional to (1) temperature history, (2) age of the sediments, and (3) organic-matter content of the sediments from which the gas originates (Claypool & Kaplan 1974, Rice & Claypool 1981). These relations suggest that the higher hydrocarbons present in microbial gas are attributed to initial diagenetic rearrangements of kerogens (Claypool & Kaplan 1974), which may happen to accompany or trail microbial methane production. This assumption is supported by the generally exponential increase in ethane/methane ratio as well as gradual increase of $\delta^{13}C1$ values with depth (Claypool & Kaplan 1974, Rice & Claypool 1981, Schoell 1983, Mattavelli *et al.* 1983).

Unfortunately, this gradual change in gas composition precludes a distinct discrimina-

tion between microbial and “diagenetic” or “late bacterial” gas (Bernard *et al.* 1978, Schoell 1983). A more recent study from Hinrichs *et al.* (2006) at Pacific ODP Sites reports on the successful isolation of both C2 and C3 traces sorbed to the sediment matrix (at 0–400m burial depth) that yielded carbon isotopic ratios as low as -70 ‰; a first clear indicator for microbial C3 production.

Systematics in hydrogen isotope fingerprints of shallow methane samples have long been the basis for the classic conception of a predominant limnic/brackish acetate fermentation pathway whereas methanogenesis via CO_2-reduction was exclusively designated to anoxic and sulphate-free marine sediments (*e.g.* Rice & Claypool 1981, Whiticar *et al.* 1986, Whiticar 1999). However, it appears now that these models have not taken into account that H is in fact highly reactive and therefore prone to species interchange (Schimmelmann *et al.* 1999), and an increasing number of critical works imply that the supposedly characteristic CO_2-reduction fingerprint in empirical $\delta D1/\delta^{13}C1$ diagrams can well be implemented by H-interchange during acetate methanogenesis (de Graaf *et al.* 1996, Wellsbury *et al.* 1997, Clayton 2010). Further, studies from Vieth *et al.* (2008) on sediments from the Waikato Basin, New Zealand, demonstrate that water extraction not only from coals but also low TOC mudstones and sandstones has the potential to release sufficient low molecular weight (LMW) organic compounds (incl. acetate) to feed the local deep biosphere.

Syntrophic microbial communities Commonly, methanogens are associated with nutrient diffusion from mud-rich sediments (Fredrickson *et al.* 1997, Krumholz *et al.* 1997 & 1999), with supply of CO_2, H_2, and acetate depending on the inorganic and microbial fermentation of sedimentary OM (Horsfield *et al.* 2006, Routh *et al.* 2001; Fig. 2–5).

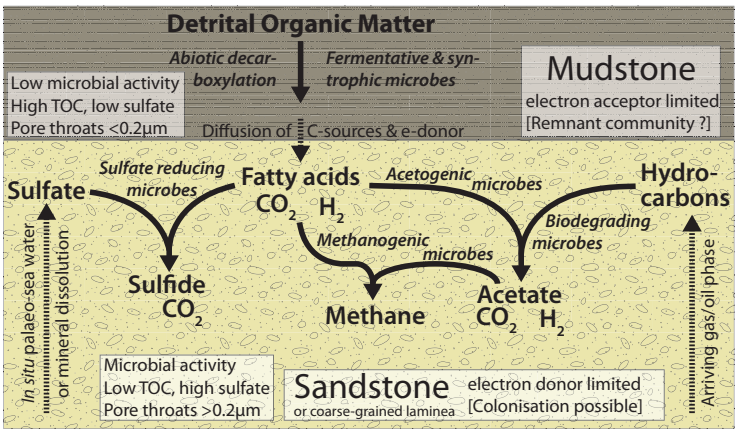

Figure 2–5 Diffusive transport of organic acids and H_2 from fermentation in low-permeability mudstones provides electron donors to anaerobic microbes in adjacent sandstones and coarse-grained interlayers where electron acceptors such as sulfate and CO_2 are available. If sulfate is absent, prevailing CO_2 sources are abiotic decarboxylation of kerogen and potential hydrocarbon biodegradation (amended after Fredrickson & Balkwill 2006).

Alternatively, methanogens may dwell at the water contact of petroleum accumulations (GWC or OWC respectively) in a syntrophic relationship to bacteria that produce acetate, CO_2 and H_2 from fermentative biodegradation of hydrocarbons (Pallasser 2000, Jones *et al.* 2008) under equally anaerobic conditions (Aitken *et al.* 2004). Methane production

associated with "methanogenic biodegradation" is also known as "secondary microbial methane" (Scott *et al.* 1994) and was reported to be dominated by the CO_2-reduction pathway (Jones *et al.* 2008).

The common association of biodegrading microbes with a gas-water contact (GWC) or oil-water contact (OWC) at the base of petroleum accumulations foster their metabolic need of an aqueous environment that has physical contact to both (1) fresh hydrocarbon phases (e-donors) entering the pore space and (2) the nutrient/oxidant-supplying fermentation of organic matter in the surrounding rock matrix. Fermentation products may also be indirectly tapped via migration along well-connected filaments of aqueous phase. Accordingly, if all other environmental prerequisites are met, petroleum biodegradation must occur within a depth interval that is restricted downwards by decreasing hydrocarbon saturation and upwards by decreasing water saturation, eventually terminating as the wetting phase changes from water to petroleum.

Interestingly, the core image database of the case study reveals several sandstone sections that show contamination with an unidentified black coating (Fig. 2–6). Although not further investigated the chemical nature of the dark material may well constitute aromatic residue (tar) from palaeo-oil degradation prior to immersion of the source rock(s) into the gas window. Accordingly, this phenomenon marks the level of palaeo-GOCs and will have led to a significant degree of pore clogging with implications on reservoir capacities and permeabilities at present. It would also demonstrate that microbial activity at a GWC may be vertically restricted to a zone of roughly 10 cm.

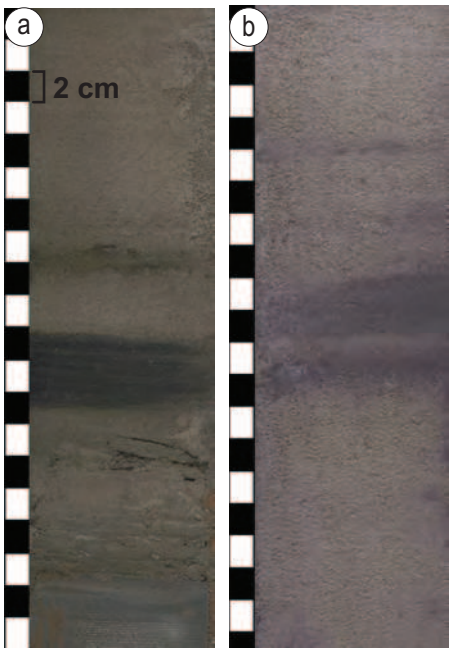

Figure 2–6 Unidentified black coating associated with palaeo-GOC in (a) Well B19 at 1719.2-1719.6 m and (b) B24 at 2058.25-2058.65 m.

In general, all these findings reflect a much stronger environmental and thus – on a basin scale – spatial restriction for anaerobic biodegradation compared to methanogenesis. Alternative anaerobes such as Fe, N, and S-reducers have been attested only a minor role in deep reservoirs. Exceptions include petroleum systems within reach of evaporites (Röling *et al.* 2003) where H_2S production may strictly inhibit biodegradation (Peters & Fowler 2002), and culmination of species that reduce Fe^{3+} directly from smectites (Kashefi *et al.* 2008).

2.3 Deciphering the migration history of a gas

Subsurface fluid samples may give evidence about their evolution only if chemical fingerprints can be explicitly linked to at least one inheritant process. Ideally, such chemical proxies can be read as progress reports on thermal gas maturity, secondary microbial alteration, and microbial gas contamination (as discussed in the previous section). The spatial distribution of such phenomena along borehole intervals may yield causal insights into the processes that effected the dispersion of pore fluids. Additional information from compositional and isotopic gas imprints that refer directly to transport mechanisms – such as adsorption and diffusion – are briefly reviewed in the following paragraphs.

Segregative Migration The debate about the existence or the importance of isotopic and chemical fractionation during migration (*e.g.* Prinzhofer *et al.* 2000b – and references therein) has recently passed its 40th birthday. While experimental evidence of fractionation is already conclusive and seems to be acknowledged by the majority of authors, the real issue nowadays is the extrapolation to natural systems (Prinzhofer & Pernaton 1997). Considering the processes involved, on the one hand, transport of a free gas phase entirely due to buoyancy has no impact on its molecular or isotopic composition (*e.g.* Zhang & Krooss 2001, Bouchard *et al.* 2008a,b). On the other hand, however, accompanying processes such as diffusion and adsorption-desorption may lead to molecular and/or isotopic gas fractionation that falls under the general term of segregative migration (Prinzhofer *et al.* 2000b). In fact, experimental studies by Pernaton *et al.* (1996) have shown that these two phenomena predominantly affect $\delta^{13}C$ and δD of the methane fraction during transport through porous rocks because methane is the most soluble HC in aqueous solution (see also Prinzhofer & Pernaton 1997).

Considering the potential of hydrocarbon adsorption-desorption, it has been shown by pioneering work of Friedrich & Jüntgen (1972) that coal layers preferentially adsorb (1) ethane relative to methane and (2) $^{13}C1$ relative to $^{12}C1$ by up to $\Delta^{13}C_{max} \approx 20$ ‰. Since then it has become widely accepted that a hydrocarbon gas migrating through porous rocks produces a gas that will be enriched in methane, and this methane is prone to ^{12}C enrichment with diffusion-related fractionation factors reported to range between 0 and >11‰ for water-dissolved methane dependent on experimental setup (*e.g.* Galimov 1975, Fuex 1980, Pernaton *et al.* 1996, Prinzhofer & Pernaton 1997, Zhang & Krooss 2001). Zhang & Krooss (2001) reported a steady-state equilibrium threshold for ^{13}C depletion in diffused methane that mainly varies with TOC content of the cap rock cross-section. However, non-equilibrium conditions prevail in natural environments (Risk & Kellmann

2008). A more complex behaviour than for carbon is observed for methane hydrogen isotopes, which are heavier in the first diffused gas, but finally become lighter than the source (Pernaton *et al.* 1996). In contrast to Friedrich & Jüntgen's (1972) adsorption-related isotope effects the impact of diffusive fractionation seems to be at least an order of magnitude lower for ethane compared to methane (Zhang & Krooss 2001, Lückge *et al.* 2002), presumably due to both (1) decreasing hydrocarbon solubility with increasing carbon number and (2) smaller molecular weight differences between isotopically heaver and lighter C2+ hydrocarbon species compared to methane

The relative magnitude and contribution of both adsorption and diffusion effects depends on the rock volume, TOC content, and effective porosity supplied on the gas migration pathway as well as the overall fraction of diffused gas compared to advected gas (Zhang & Krooss 2001, Prinzhofer & Pernaton 1997), but no successful quantitative approaches on associated isotope effects have yet been published (Prinzhofer *et al.* 2000b). Particular challenges for such descriptive models are variations in the methane isotope fractionation effect that result from (1) the respective interactions of methane with the rock matrix (*i.e.* relative importance of Knudsen diffusion *versus* molecular diffusion) and (2) from the variable molecular bonds between water and methane (Pernaton *et al.* 1996, Prinzhofer & Pernaton 1997). Comparably variable isotopic shifts were observed for CO_2 and also N_2 migration through dry sandstone impregnated with organic liquids (O'Leary 1984, Cerling *et al.* 1991, Hoering & Moore 1958).

Established advection-diffusion models were designed to track evidence of diffusive permeability contrasts *vs*. carbon isotope fractionation of hydrocarbon (HC) compounds by cross-plotting concentration *vs*. isotope ratios (Prinzhofer & Pernaton 1997; Fig. 2–7).

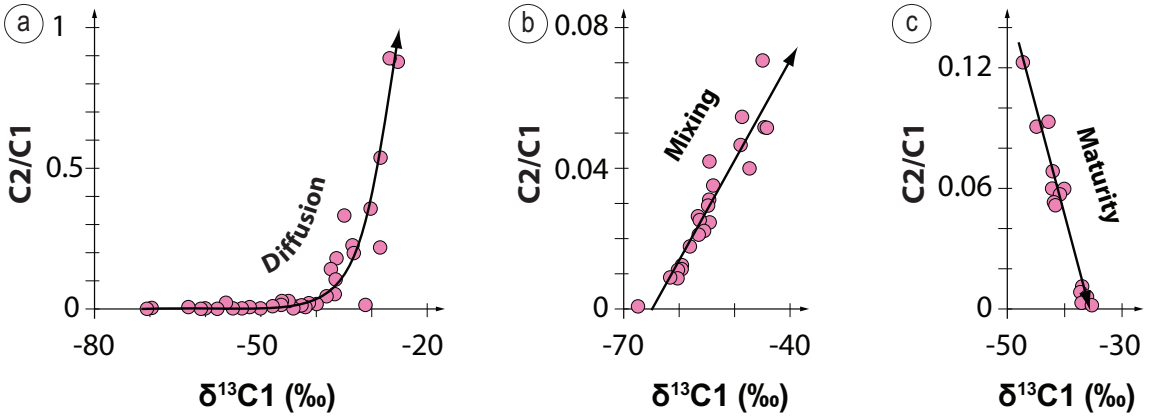

Figure 2–7 Gas chemical evolution paths associated with (a) diffusion in German coals, (b) mixing of thermogenic and microbial Apulian gases, and (c) thermogenic source maturity in gases from the Delaware Basin (graphical reproduction from Prinzofer & Pernaton 1997 – and references therein).

However, Zhang & Krooss (2001) argue that this approach is only applicable if a large fraction of the recovered methane sample has migrated via diffusion since the ascribed

^{13}C1 depletion would be obliterated if large quantities of non-diffused gas were admixed. This approach is applicable only to a limited extent to the Pliocene gas in Nile Delta for two reasons: (1) concentration ratios within the case study are extreme due to C1 dominance and are hence error-prone, and (2) there may be too many background effects on isotopic ratios involved, *e.g. in situ* microbial gas generation.

Alternatively, subtraction of the microbial methane fraction from the sampled gas data will be demonstrated to yield a key indicator for deciphering gas mixing mechanisms. Moreover, the role of diffusive HC loss will be investigated with the aid of a newly designed saturation model in Part III.

Synopsis of Chapter 2 The principles of thermogenic gas generation from organic matter in deep source rocks are well understood. In contrast, environmental constraints and metabolism of syntrophic microbial communities within the deep biosphere is a field of active research. Extremely low H_2S concentrations in the recovered gas samples suggest that most of the Plio-/Pleistocene hydrocarbon system is buried beyond the sulfate-reduction zone. The underlying methanogen zone incorporates archaea that produce low-molecular weight hydrocarbons (C1-C3) and have been suggested to partly collaborate with wet gas (C2+) biodegrading bacterial communities.

Isotopic evolution of both biodegraded (C2+) and thermogenic (C1+) hydrocarbons can be explained by the kinetic isotope effect (KIE). In contrast, microbial hydrocarbon waste products may have a quite narrow range of carbon isotopic ratios dependent on variations in the source composition. The primary genetic mixture of a gas can be unravelled by microbial/thermogenic end-member discrimination because evidence about sulfate-free anaerobic methane oxidation has not yet been reported in the literature. In terms of potential migration mechanisms the recognition of diffusive hydrocarbon loss in the case study may be equivocal due to the extreme methane dominance of the system.

While the identification of gas chemical migration proxies within the case study is presented in Chapter 3 a more specific well-by-well discussion under consideration of lithology and HC saturation will conclude this work in Part IV.

Chapter 3 Nile Delta: The gas story

Both seismic-scale gas accumulations and background gas concentrations as detected in the drilling fluid invoke the fundamental questions for hydrocarbon provenance and flux rates in the shallow Nile Delta petroleum system. To date petrophysical analysis has neither the power nor the resolution to decipher the genetic and secondary history of *in situ* gases. A detailed analysis of gas geochemical patterns from recovered fluid samples is therefore essential.

This chapter deals with the information that is encoded in geochemical gas fingerprints to infer general insights on the movement of gas in the subsurface. As mentioned before, detailed interpretation of the herein inferred geochemical migration tracers in context of both lithology (Part II) and gas volumetrics (Part III) is subject to Part IV of this thesis.

3.1 Data provenance and quality control

The BP Group has kindly provided analytical gas and fluid data sets from a variety of their Plio-/Pleistocene Nile Delta boreholes (Chapter 1). Compositional and isotopic analyses were conducted by Isotech Laboratories Inc. The following conventional sampling techniques were used:

Flame Ionisation Detector FID is a type of gas chromatograph (GC) that surveys the total gas (TG) concentration and composition via voltage change during combustion. It is vacuum-connected to a container ("possum belly") that collects the outflowing drilling mud prior to recycling. Measurements take place once every 30-90 seconds and yield average gas concentrations per formation volume equivalent to ~1m drillbit penetration. The high sampling rate leads to a low analytical quality: issues involve preferential methane loss and baseline shifts as a function of both flowline circulation rate and drillbit penetration rate. No isotope data is collected.

Headspace Gas HSG was sampled from the headspace of sealed cans that contain drill cuttings recovered from the shale shaker and left to diffusively equilibrate. Laboratory analyses usually include both compositional and isotope chemistry that may both be severely affected by desorption effects and diffusive methane loss during storage (*e.g.* Risk & Kellmann 2008). Sampling rates are generally low.

Isotubes Isotube data relate to laboratory analyses of mudgas samples that were

diverted from the vacuum tube that connects the "possom belly" with the FID (see above). Closed-system sampling is responsible for a much higher quality compared to HSG data. Methane to propane composition is generally similar to RFT/MDT measurements (see below) but butane and higher hydrocarbons can be depleted due to their lower vapour pressure. "Isotube in" data is sampled from the recirculated drilling mud in order to check the regular "Isotube out" samples for compositional effects of gas recycling upon reinjection into the borehole. Sampling rates vary between 3 to 60m depending on the operator and depth resolution is estimated around an average of 3m.

Repeat Formation Tester RFT such as Schlumberger's Modular Dynamics Formation Tester (MDT) are wireline tools that probe the mudcake at the borehole wall and conduct various *in situ* measurements (*e.g.* pore pressure and formation temperature) as well as collect fluid samples for laboratory analysis. Sampling rates are usually low but downhole data acquisition techniques yield the highest available quality in precision, accuracy, and resolution in terms of both analytics and reference depth (logger's depth, see Chapter 1.3). Such downhole data sets have the lowest risk of atmospheric gas contamination and therefore yield the most accurate cross section of non-hydrocarbon trace components (Fig. 3–1). Hydrogen sulfide content within the sampled temperature interval is in general very low and completely missing in case of the samples from the four priority wells B19, B20, B22, and B24 (20 samples in total, data not shown). These findings confirm that the recovered gases represent genuine samples from the methanogen zone of the deep biosphere (see Fig. 2–3) including the full spectrum of microbial mediation processes that are discussed in Chapter 2.

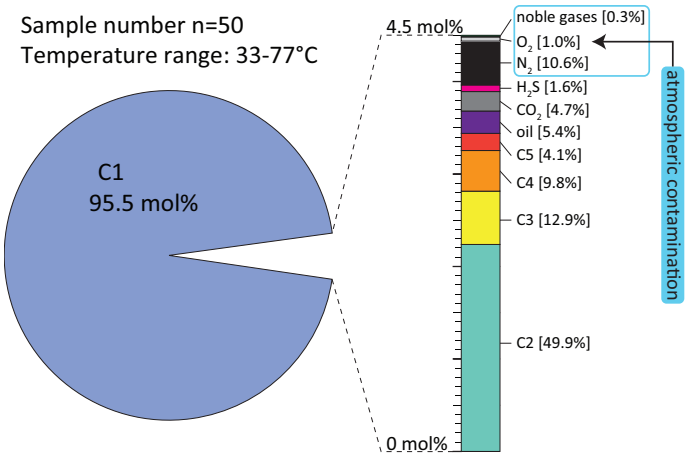

Figure 3–1 Average fluid composition of MDT samples. The presence of oxygen implies that a minor degree of atmospheric contamination has occurred before the mudcake sealed the formation from the borehole circulation fluid. Values in brackets indicate fractions of the non-methane components.

Quality Control The gas data quality of the different acquisition techniques can be assessed by comparison of the respective analytical magnitudes (Fig. 3–2). The best compromise between sampling rate and similarity to MDT reference data both in compositional and isotope values is clearly given by the Isotube (out) samples. In contrast, data from the partially desorped HSG samples are notably enriched in wet gases and up to

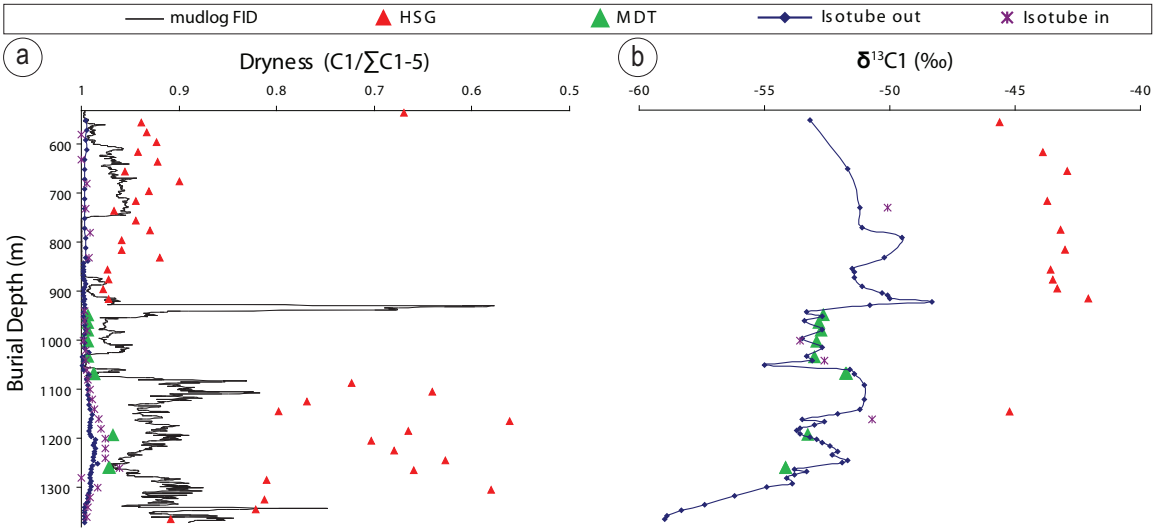

Figure 3–2 Analytical differences in both (a) hydrocarbon compositional and (b) isotopic measurements suggest that "Isotube out" samples have the highest resemblance of *in situ* MDT reference data (example from Well B19). Samples acquired from FID, HSG, and "Isotube in" methods were therefore neglected in the gas geochemical interpretations of this study.

8‰ heaver in $\delta^{13}C1$ compared to predominantly interstitial gases that were recovered by other sampling techniques (Fig. 3–2). Such observations would comply with the findings of Friedrich & Jüntgen (1972) and Whiticar (2002) of preferential wet gas and heavy carbon isotope adsorption to organic matter. Alternatively, both compositional and isotopic shifts could as well be explained by diffusive methane loss from the sample container prior to measurement, *i.e.* the degree of methane desorption upon sediment fragmentation during drilling remains unresolved in this study. Abundances of the reliable Isotube and MDT/RFT data are considered in the data overview distributions (Fig. 1–6) whereas the poor quality samples are not further considered in the remainder of this study.

Hydrocarbon compositions of the high quality gas samples are to more than 99% dominated by methane (Fig. 3–3a). Generally low wet gas concentrations demand the application of lower-limit cut-offs for quality control of associated isotope analyses. While a general minimum of 5 ppmv was chosen for medium quality isotope data good quality is expected above the following thresholds: 1000 ppmv C1 20 ppmv C2, 10 ppmv C3-5

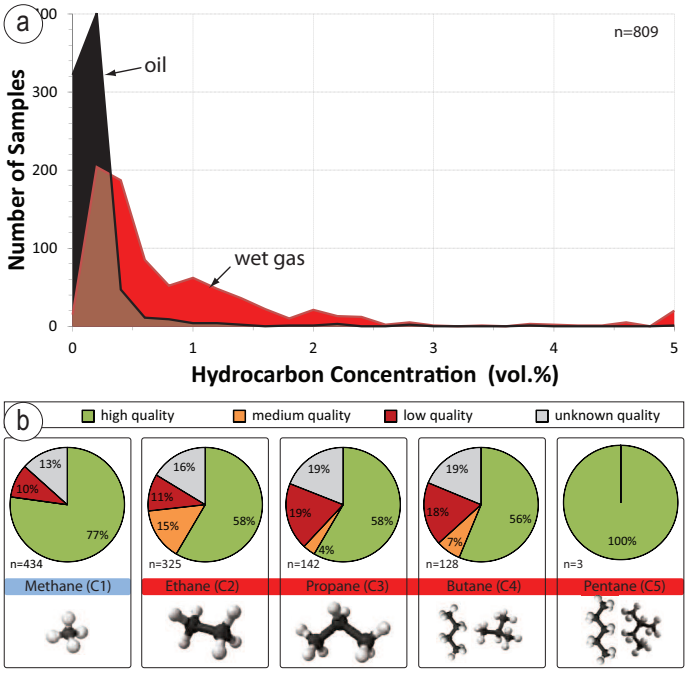

Figure 3–3 (a) Distribution of wet gas (C2-5) and oil (C6+) composition of the high quality fluid samples from the case study. (b) Carbon isotope data quality of sampled methane and wet gas as a function of lower-limit concentration cut-offs (see text for details).

(Fig. 3–3b; T. Dodd personal communication).

3.2 Mixing of genetically different gases

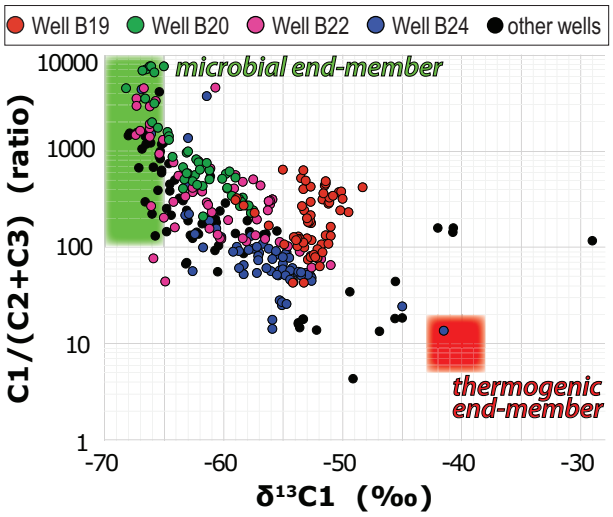

Figure 3–4 The primary origin of the entire Plio/Pleistocene gas data set can be discriminated into microbial and thermogenic gas, while genetic mixtures can be visualised in a Bernard-type diagram.

The omnipresence of a genetic gas mixture ranging between the common allocations of microbial and thermogenic gas fingerprints is shown in a classic Bernard-type diagram (Fig. 3–4; Bernard *et al.* 1978). Inevitably, quantification of these mixtures requires an adequate definition of the end-member gas fingerprints. These are a function of initial isotopic composition and maturity of the kerogen precursor.

In fact, it would be of great benefit to assess the thermogenic gas maturities along the wells. Such information would imply the relative timing of generation and entrapment, and the presence of vertical migration fronts would be spotted. Unfortunately, the pervasive microbial activity alters the isotope data to such an extent that classic gas maturity models become inapplicable (*e.g.* Berner & Faber 1996; Fig. 3–5). Accordingly, our attention must be drawn to the architecture of the shallow Nile Delta microbial system before a suitable end-member dissection of the sampled gas evolution can be established.

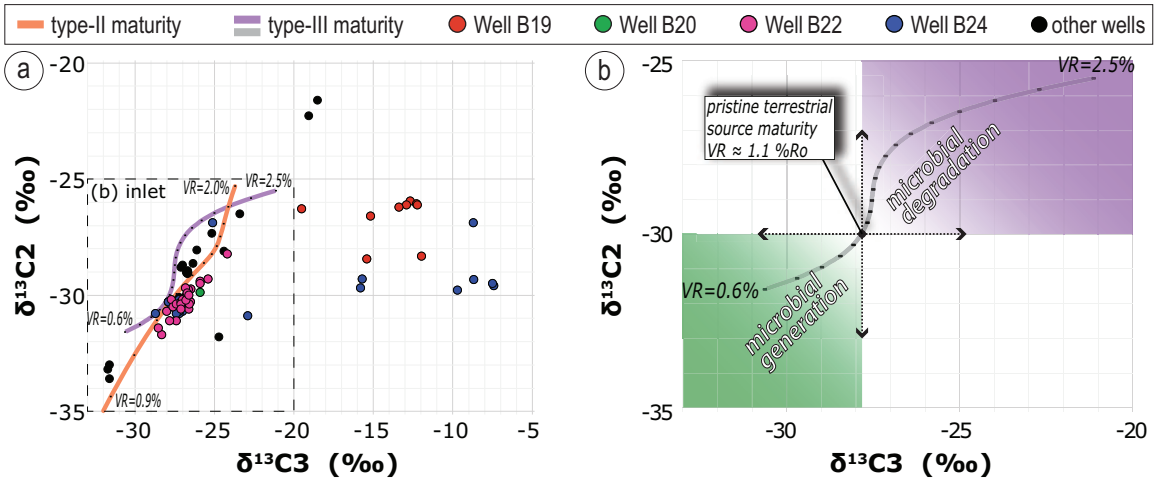

Figure 3–5 (a) Maturity pathways of type-II and type-III kerogen source rocks from the experimental model of Berner & Faber (1996) were both fitted to the bulk data set with a static source carbon isotope ratio of -29‰. The broad range of apparent thermogenic gas maturities do not comply with the narrow maturity range as proposed by δ^{13}C-iC4 ratios (see text) and Vandré *et al.* 2007. (b) Consequently, deviations from the proposedly pristine gas maturity fingerprint (~1.1 %Ro; Vandré *et al.* 2007) are allocated to substantially biodegraded gas that blends into recharge with fresh thermogenic gas and *in situ* microbial gas generation. The partial overlap of these secondary processes precludes an exact tracing of the carbon isotope alteration pathways for each individual point of the displayed bulk data set.

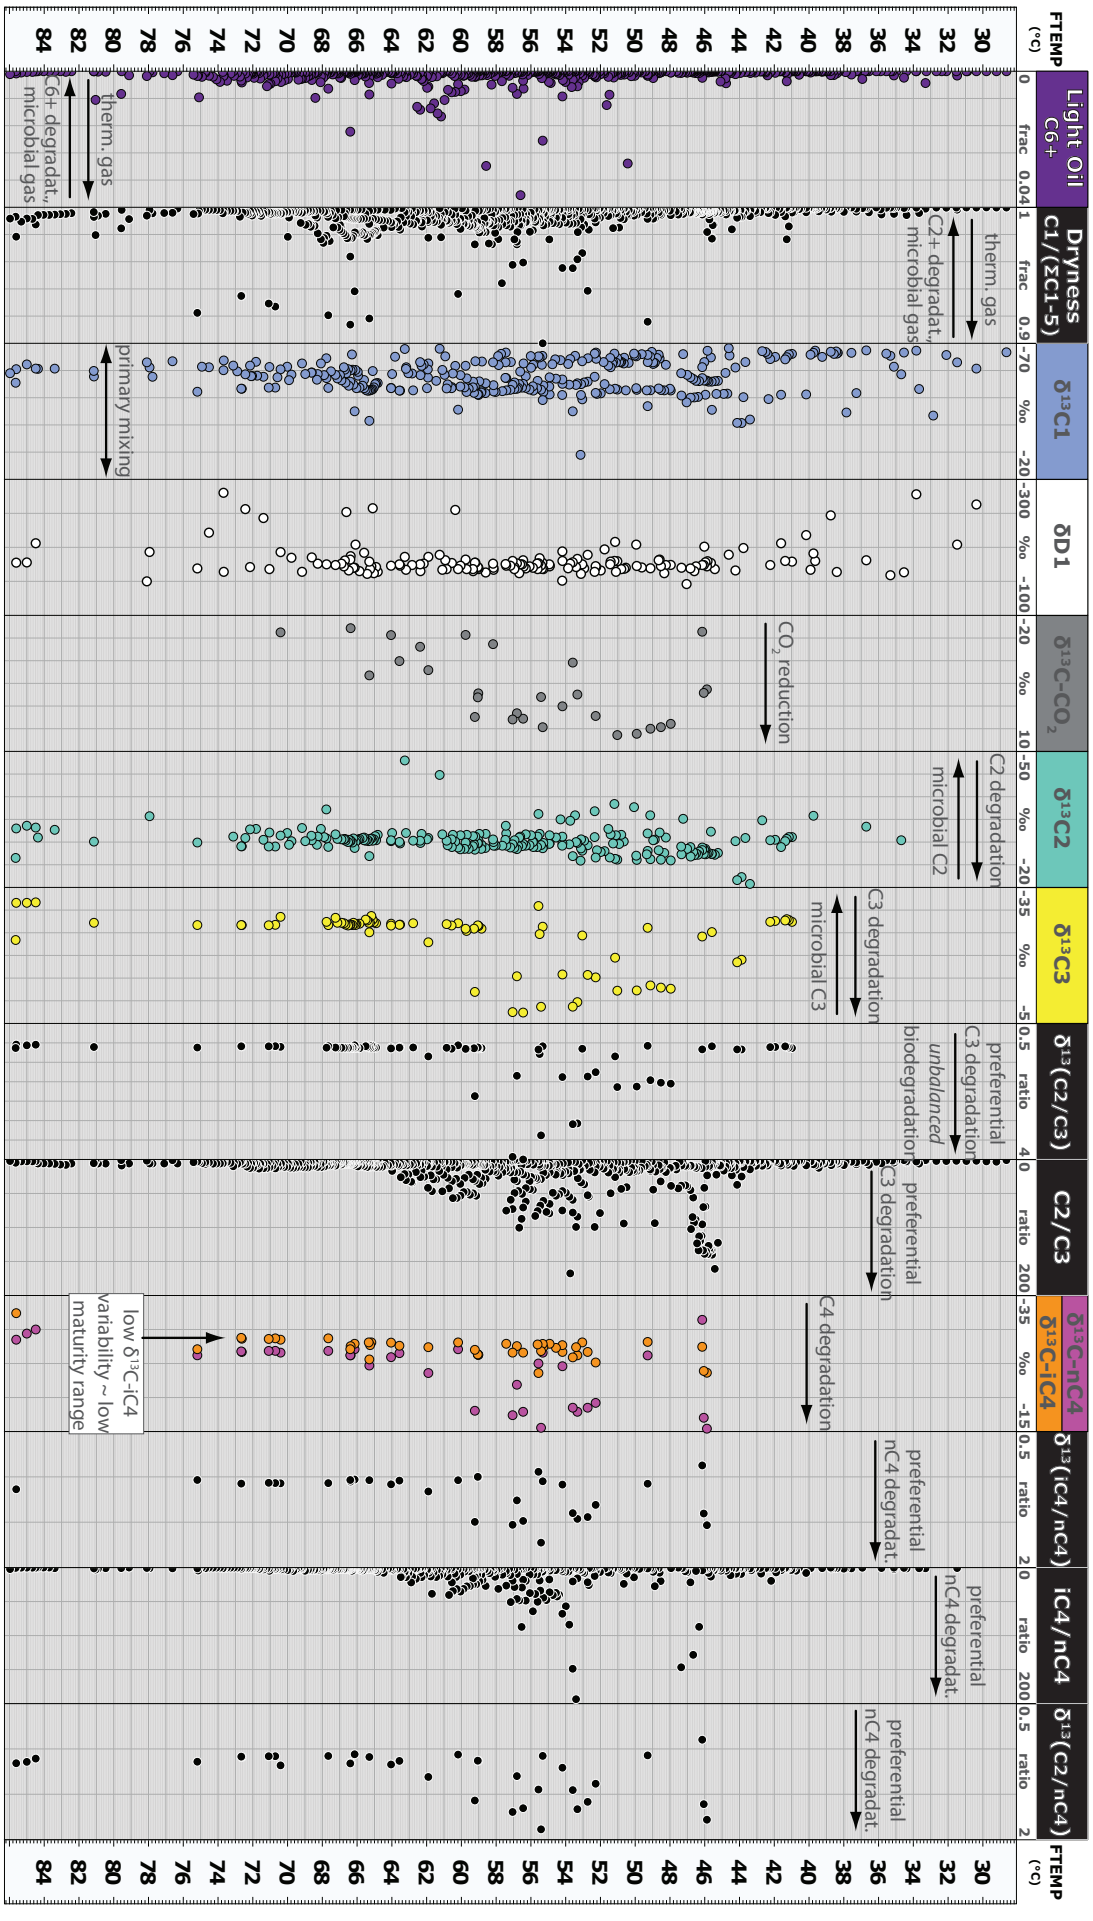

Figure 3–6 Formation temperature profiles of selected gas compositional parameters and isotope ratios from the bulk Plio-/Pleistcene data set. See text and Figure 3–7 for disambiguation of *unbalanced* (methanogenic) biodegradation and general discussion.

Evidence of microbial activity The impact of microbial activity as a function of temperature can be deduced from the relevant bulk isotope data sets in Figure 3–6. Here, the bulk of the methane hydrogen isotopic ratios (δD1) are in close proximity to the proposed maximum value for the methanogenic CO_2-reduction pathway (-170 ‰; Whiticar 1999; see Chapter 2.2). Iso-butane carbon isotopic ratios (δ^{13}C-iC4) are likewise almost constant irrespective of burial depth (~temperature) and confirm a small range of thermogenic gas maturity as suggested by Vandré *et al.* (2007) because iC4 is rather resistive to microbial attack as opposed to nC4 (*e.g.* Kniemeyer *et al.* 2007, Abrakasa 2009).

iC4-to-nC4 and especially the ethane-to-propane carbon isotope ratios visualise the maximum relative activity of C3+ biodegradation – at roughly 55°C. As discussed earlier in Chapter 2.2 such fermentative wet gas isotope overprint is traditionally associated with the gas-water contact (GWC). This classic interpretation can be confirmed by the observation that most of the degraded propane is associated with seismic-scale accumulations (Fig. 3–7a). The presence of this microbial overprint in some of the seal sections therefore implies that previously accumulated gas has entered the mudstone pore space (Fig. 3–7a). Likewise, the complete absence of palaeo-biodegradation in the Lower Pliocene accumulations implies that the pore space has been flushed with fresh gas at some point during the last ½ Ma – considering the average burial rate in this area (Chapter 1.1).

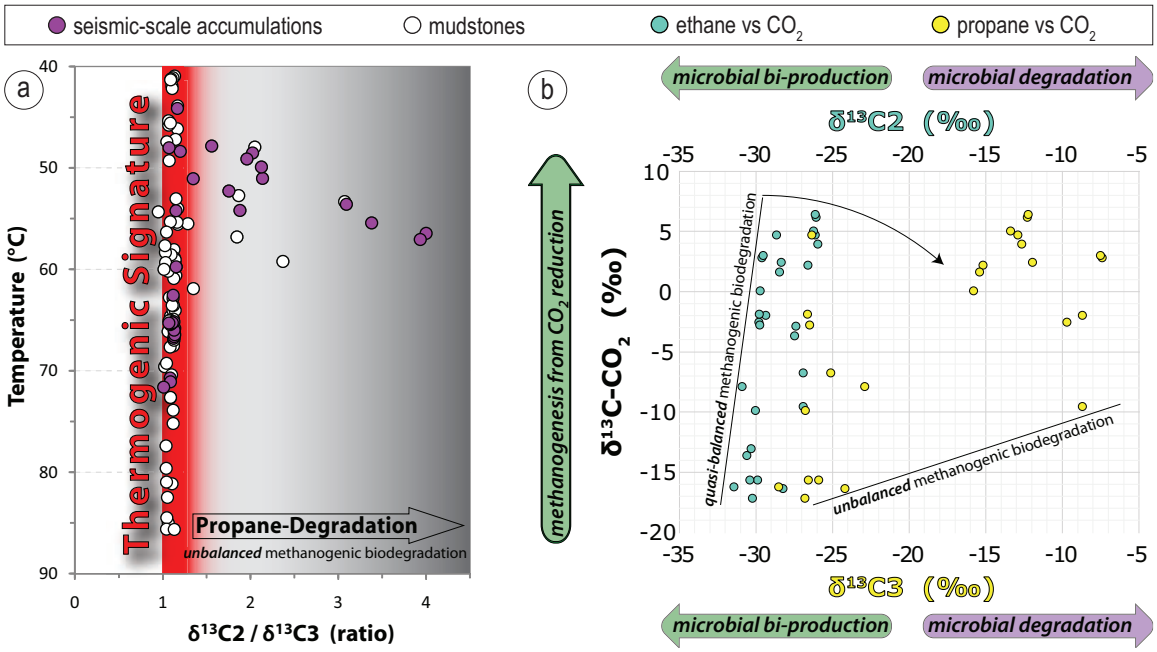

Figure 3–7 (a) Propane biodegradation focusses in accumulations and some mudstone units in the Upper Pliocene section (T<60°C). However, no such isotopic traces of palaeo-degraded gas have been measured in the Lower Pliocene. (b) The co-presence of both ^{13}C-enriched propane (from biodegradation) and carbon dioxide (from methanogenesis) confirm that syntrophic methanogenic biodegradation processes take place in the deep biosphere. As there is no evidence of isotopically light microbial propane production that would counterbalance the biodegradation isotope shift this process may be called unbalanced or normal methanogenic biodegradation. In contrast, slightly ^{13}C-enriched ethane with increasing δ^{13}C-CO_2 suggests microbial attack on ethane that is largely compensated for (*i.e.* quasi-balanced) by extremely isotopically light microbial ethane production ($\delta^{13}C2_m \leq$ -55 ‰).

Relative impact of microbial wet gas generation vs. consumption However, evidence will be presented in Chapter 3.4 of this study that indicates biodegradation of both molecular C2 and C3 as a function of temperature regime and influx mechanism of the thermogenic hydrocarbons. The remarkably high wet gas isotope ratios in Figure 3–6 and 3–7a will be allocated to a disbalance between ethane and propane degradation that is introduced by extreme molecular C3 depletion (heavy δ^{13}C3) and isotopically light C2 from prevalent syntrophic microbial generation. These considerations support the distinction between "classic" or unbalanced methanogenic biodegradation of propane (preferential C3 depletion with heavy δ^{13}C3, no counterbalance from microbial C3 production) and quasi-balanced methanogenic biodegradation of ethane (C2 depletion but mostly unaffected net δ^{13}C2 due to contemporary microbial C2 production).

There is no evidence that metabolic pathways and hence microbial community structures differ between quasi-balanced and unbalanced methanogenic biodegradation; it is just that the relative impact of the two opposing KIE of wet gas production *versus* consumption is likely to be partitioned by an extrinsic factor, fostering a disbalance at the GWC in favour of a net degradation fingerprint (heavy δ^{13}C3). In fact, extreme C3 depletion as illustrated in Figure 3–7a suggests that thermogenic recharge is currently (or has until recently been) both persistent and sufficiently high to maintain the metabolic turnover of GWC dwellers in favour of the biodegradation pathway rather than methanogenesis.

More elaborate proof on this subject will be presented later in this chapter. For the moment a first clue on the proposed quasi-balanced and GWC-independent biodegradation is given by differences in the temperature span of wet gas isotope ratios (*e.g.* δ^{13}C2/δ^{13}C3 and δ^{13}C-iC4/δ^{13}C-nC4) and their molecular equivalents (*e.g.* C2/C3 and iC4/nC4) in Figure 3–6. Further, a strong isotopic indication that the associated biodegradation mechanism is coupled to methanogenesis to variable extent is presented in Figure 3–7b.

Irrespective of the extent to which isotopic biodegradation fingerprints may be compensated for by syntrophic microbial gas generation it should be noted that the rather confined interval of unbalanced microbial activity (as emphasised in Figure 3–7a) poses a remarkable contrast to the omnipresence of microbial methane (see light δ^{13}C1 in Fig. 3–6). So the obvious question is why would there be remnants of palaeo-microbial methane at depth although there is not the slightest evidence of contemporary unbalanced biodegradation? Apart from the possibility of quasi-balanced microbial overprints it could be suggested that a significant fraction of the palaeo-microbial gas buried beyond the methogenesis temperature window is being retained in the pore space – by processes such as dissolution, adsorption and capillary entrapment – while the palaeo-biodegraded gas has been flushed out. By analogy, a similar phenomenon of microbial gas retention

would be expected to take place during reservoir leakage upon capillary failure of the seal. Either way, intrusion of unbalanced biodegraded gas into the mudstone seal sections in Fig. 3–7a must have occurred rather recently since it has not yet been overprinted by dilution effects.

Key implications for resolving the gas history So far it has been shown that microbial production and consumption effects seem to have a strong grip on the gas geochemical and isotopic composition. In contrast, pristine thermogenic gas geochemistry seems to be rather consistent owing to a low maturity range which is, however, disguised by the microbial activity in the post-Messinian sediments (Fig. 3–5). This is very useful information because a narrow thermogenic end-member allows a relatively rigid estimate of the thermogenic methane fraction for each sample, *i.e.* variations in $\delta^{13}C1$ are neither subject to differential gas maturities nor exposed to microbial attack but predominantly affected by the degree of thermogenic/microbial gas admixture. Therefore, subtraction of the microbial methane contamination from the bulk gas fingerprint based on $\delta^{13}C1$ will help to elaborate on the suspected co-existence of methanogenic and wet gas biodegrading microbes within the non-reservoir.

3.3 Isolation of primary source fingerprints

The degree of thermogenic gas intrusion along the boreholes is a direct measure of the minimum fraction of *ex situ* gas in the pore space. This chapter demonstrates how primary geochemical fingerprints from microbial and thermogenic gas generation can be dissected in order to decipher subsurface gas movement.

Microbial background production As mentioned in Chapter 2.2 the optimum temperature range for methanogenesis is 30-50°C (Zeikus & Winfrey 1976, Wellsbury *et al.* 1997). The methane carbon isotopic temperature profile of the bulk Plio-/Pleistocene gas data set indicates that the strongest microbial methane fingerprint ($\delta^{13}C1_m$ = -68‰) plots within this temperature regime and tends towards isotopically heavier C1 at greater depth (Figure 3–8). It is tempting to assume an increasing $\delta^{13}C1_m$ end-member with greater depth due to successive isotopic depletion of the source organic matter upon burial throughout and beyond the optimum methanogen window. However, methanogens under non-optimum environmental conditions would be exposed to the evolutionary pressure to economise with their energy budget and may therefore tend to have a stronger metabolic preference for the energetically favourable ^{12}C-^{12}C nutrient bonds, producing an

even lighter carbon isotopic methane than shallower methanogens. Alternatively, heavier $\delta^{13}C1_m$ below the optimum temperature window could be the consequence of decreasing metabolic rates and hence decreasing diffusion gradients across the archaean cell membrane, forcing them to feed on the organic matter fermentative products within their immediate environment which restricts their ability to select the isotopically lightest nutrients.

Since a systematic alternation of the microbial methane end-member with burial depth cannot be resolved it was decided to fix $\delta^{13}C1_m$ at the lightest measured value (-68‰) independent of temperature regime. Consequently, the temperature trend in the bulk $\delta^{13}C1$ data below the optimum methanogen activity window is allocated to decreasing *in situ* production of the same microbial gas type as above, hence suffering an increased dilution effect from isotopically heavy thermogenic methane and condensates that arrive from depth (see V-shaped data scatter in Fig. 3–8).

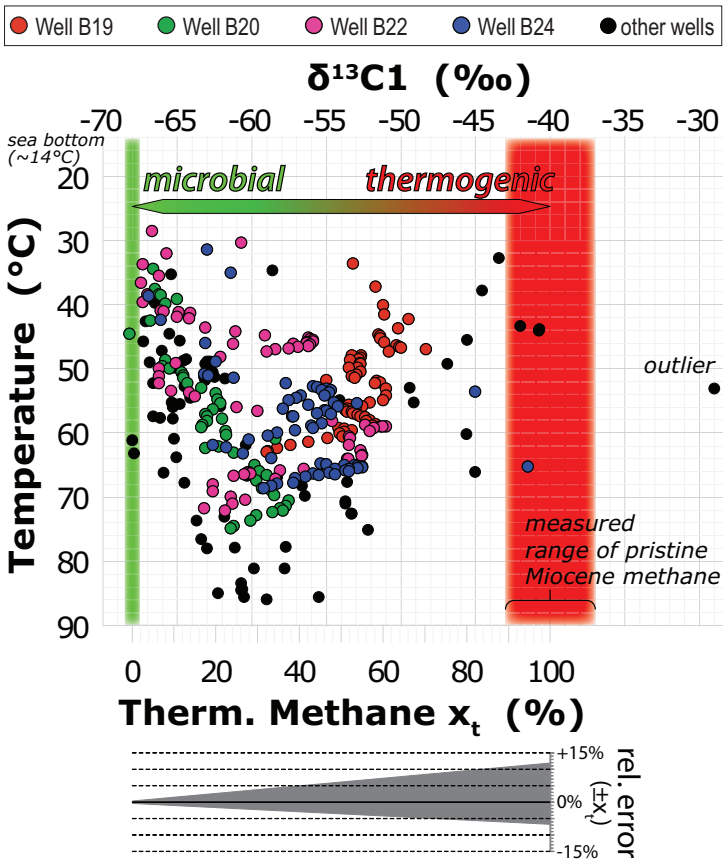

Figure 3–8 Proposed carbon isotope end-member of microbial and thermogenic methane in a binary $\delta^{13}C1$ system. Relative error of thermogenic methane fraction x_t according to end-member uncertainties (see text).

The assumption that the compositional information associated with the three lightest $\delta^{13}C1$ data points in Figure 3–8 represent pristine microbial gas allows the determination of the microbial ethane by-production. In order to avoid bias from co-evolutionary ethane biodegradation the gas sample with both the lightest methane and ethane carbon isotopic fingerprint was chosen as microbial end-member: $\delta^{13}C1_m$=-67.9 ‰, $\delta^{13}C2_m$=-48 ‰, C2=0.05 vol.%. These data fit well within the isotopic and compositional ranges of published microbial gas end-members from other gas fields around the globe as mentioned in Chapter 2.2: $\delta^{13}C1_m$ between -55 and -110‰ dependent on source composition (Whiticar 1999) whereas the lightest microbial ethane so far recovered had $\delta^{13}C2_m \approx$ -55‰ with C2 concentrations ranging between 3 ppmv and 0.9 vol.% (Davis & Squires 1954, Oremland *et al.* 1988, Lückge *et al.* 2002).

Admixture of thermogenic gas As presented in the last chapter the uncertainties in the extent of *in situ* microbial fermentation within the Plio-/Pleistocene stratigraphy have the potential not only to overwrite but also to mimic the effects of thermogenic source maturity. Pristine thermogenic gas end-members can therefore only be estimated under the assumption of a narrow maturity range for the western Nile Delta area as implied by the very low δ^{13}C-iC4 variability (Fig. 3–6).

Unpublished Miocene gas data have pristine (thermogenic) $\delta^{13}C1_t$ values around -38 ‰ with some lower values down to -43 ‰, $\delta^{13}C2_t \approx$ -28.5 ‰, and $\delta^{13}C3_t \approx$ -26.5 ‰ (T. Dodd personal communication).

Choosing the average Miocene δ^{13}C1 fingerprint of about -40 ‰ would result in a systematic error of roughly ±3 ‰, which translates into an accuracy of roughly ±10 % thermogenic gas content (see Fig. 3–8) given the entire genetic δ^{13}C1 range of Δ^{13}C1 = 28 ‰ between the apparent microbial end-member ($\delta^{13}C1_m$ = -68 ‰) and the average thermogenic end-member ($\delta^{13}C1_t$ = -40 ‰). The formula for linear mixing between the two genetic end-members is as follows:

$$x_t\,[\text{frac}] = (\delta^{13}C1 - \delta^{13}C1_m) / (\delta^{13}C1_t - \delta^{13}C1_m) \qquad \textit{(3a)}$$

with x_t being the fraction of thermogenic gas per sample. The aforementioned accuracy for this estimate will suffice as a reasonable translation of the gas genetic fingerprint into the volumetric partition of each gas sample between the two genetic sources involved.

3.4 Patterns of hydrocarbon generation and recycling

Equation 3a enables a back-stripping of the microbial methane contribution from molecular methane concentrations of the sampled gas genetic mixtures, leading to an isolation of thermogenic methane concentration $C1_t$ (Equ. 3b).

$$C1_t\,[\text{vol.\%}] = C1 \cdot x_t \qquad \textit{(3b)}$$

When working with concentration data it is important to appreciate that absolute values refer to the sampled bulk mixture of natural hydrocarbons, formation water, and borehole circulation fluids. Since the degree of sample contamination with borehole fluids is unknown (for isotube data) the only sensible way to analyse hydrocarbon concentrations is to use relative concentrations in form of molecular ratios (*e.g.* C1/C2 or C1/(C1+C2) etc.). A cross-plot of thermogenic methane concentrations from Equation 3b *versus* ethane concentrations reveals a range of distinct ratios that are roughly a function of temperature regime (Fig. 3–9).

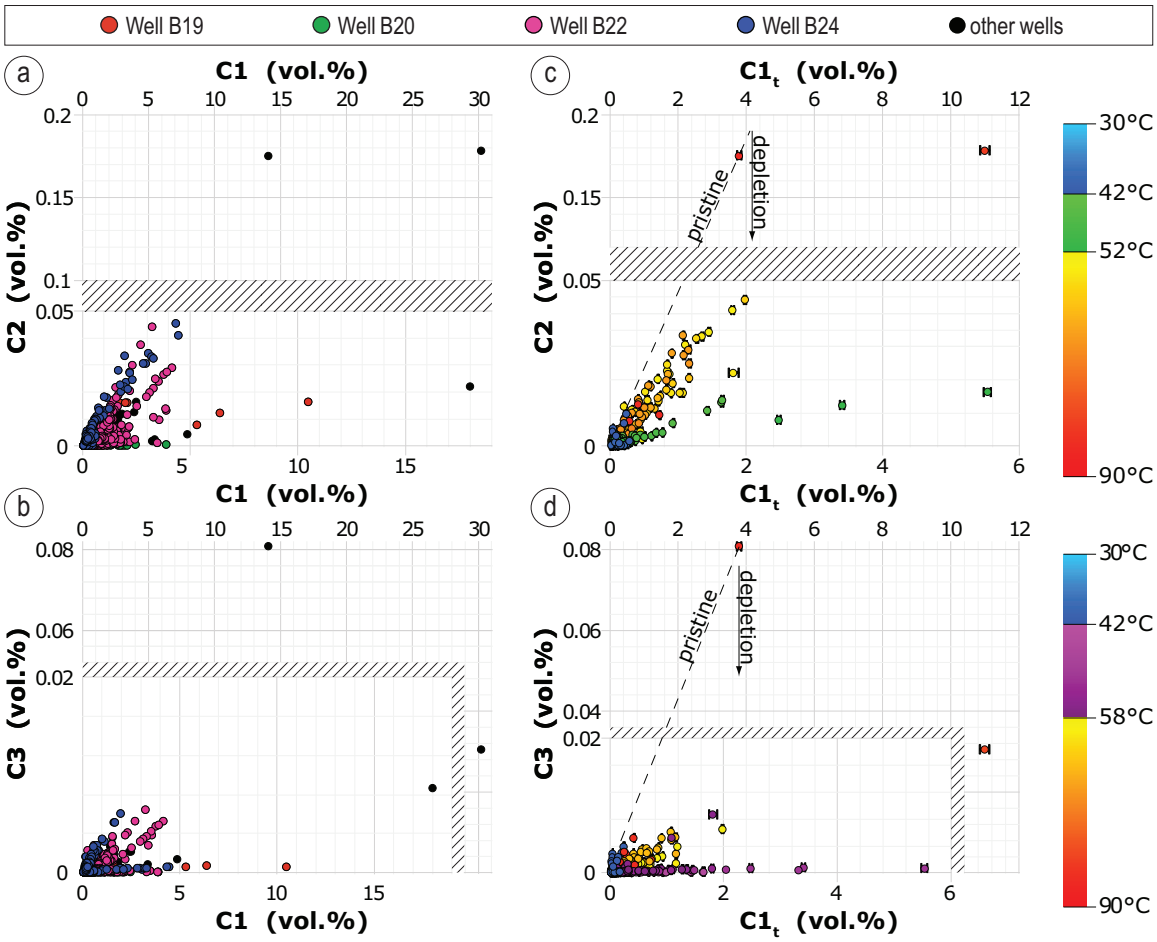

Figure 3–9 Ratios between (a) ethane and methane concentrations and (b) propane and methane concentrations converge (c,d) upon isolation of thermogenic methane $C1_t$ roughly as a function of temperature regime. The temperature windows for propane depletion differ from those for ethane depletion. Under consideration of the uncertainties exhibited by the very large scale discrepancies (see different magnitudes of x/y-axis annotations) such unique ratios can be interpreted as the compositional overprint of a restricted thermogenic gas maturity by stabilising processes such as biodegradation-vs.-recharge rate balance. Analoguous suggestions were made in the work of Tyler *et al.* (1994; see text). Error bars according to uncertainties stated in Chapter 3.3.

A similar pattern although with even stronger consistency is displayed when plotting measured C3 *versus* C2 concentrations (Fig. 3–10), confirming that the isolation of thermogenic gas by Equations 3a and 3b on the basis of the chosen gas genetic end-member definitions is a valid procedure. The suggested temperature stratifications in the bulk data set imply a likewise stratified distribution of wet gas biodegrading microbes which activity co-depends on the rate of thermogenic (wet) gas charge. Consequently, the petroleum system of the Plio-/Pleistocene Nile Delta is at least partially in balance with the activity of deep microbial communities.

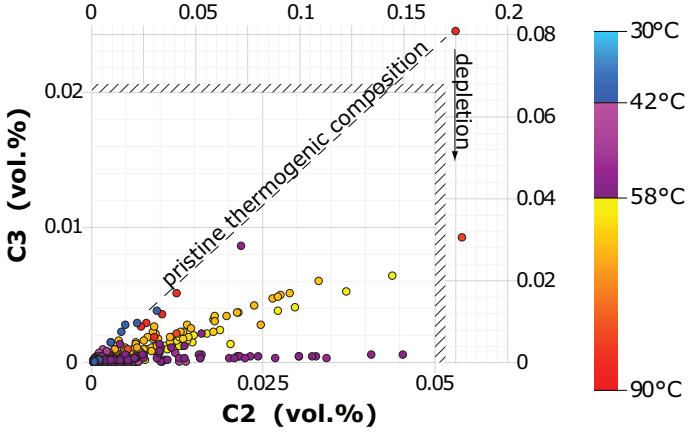

Figure 3–10 The suggested temperature trends are clearer in the case of measured ethane (C2) and propane (C3) concentrations because of rather similar scales as opposed to the large methane quantities in Figure 3–9.

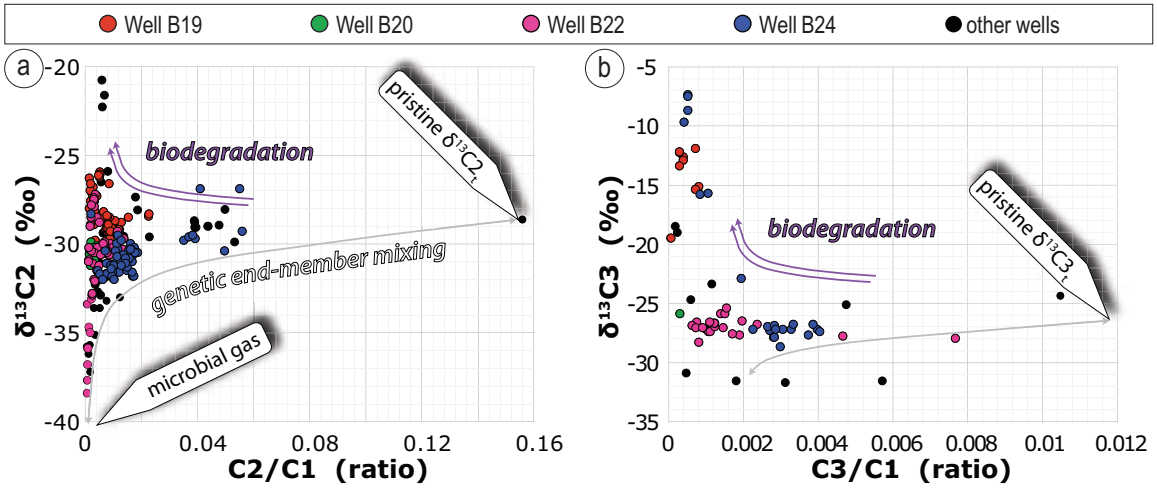

Figure 3–11 Co-evolution of carbon isotopic and compositional wet gas data from the Plio-/Pleistocene Nile Delta. ^{13}C enrichment upon compositional depletion indicates biodegradation while ^{13}C depletion is interpreted as dilution of the primary thermogenic fingerprint by microbial gas admixture (and *vice versa*). Heavy carbon isotopic overprints from wet gas biodegradation seem only noticeable after very strong compositional depletion. Likewise, the very low (trace) concentrations of microbial wet gas will be responsible for the delayed tendency towards lower (*i.e.* microbial) $\delta^{13}C2$.

Further, under consideration of the $\delta^{13}C2$ evolution as a function of relative C2 concentration C2/C1 (Fig. 3–11) it becomes clear why the apparent wet gas compositional stratification is not recognised in equivalent isotope patterns: isotopic ratios increase only significantly when most of the wet gases (in this case C2 and C3) have already been removed from the system. As anticipated in Chapter 3.2, these observations confirm that $\delta^{13}C2$ biodegradation fingerprint is partly compensated for by isotopically light microbial ethane by-production. Such mutual quasi-extinction of opposing kinetic isotope shifts – microbial ethane degradation *versus* syntrophic microbial ethane by-production (see bold arrows in Fig. 3–7b) – (1) yields a logical explanation for the poor recognition of ethane biodegradation in the literature (*e.g.* Pallasser 2000) and (2) challenges Kinnaman *et al.*'s (2007) hypothesis of preferential microbial cracking of hydrocarbons that comprise non-terminal C-atoms (C3+ chains).

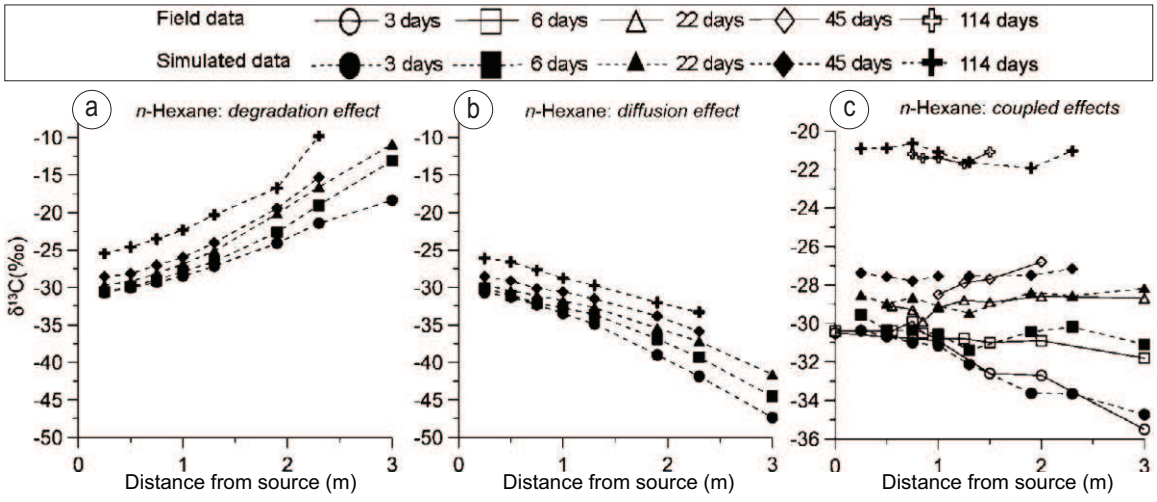

Figure 3–12 A study from Bouchard *et al.* (2008a,b) shows that the modelled carbon isotope evolution of n-Hexane for (a) aerobic biodegradation and (b) diffusion overlap to (c) a quasi-steady state bulk signal that is in accordance to the measured isotope path (open symbols). Adopted from Bouchard *et al.* 2008a.

In the literature, a similar isotopic compensation effect between (aerobic) biodegradation and molecular diffusion has been described by Bouchard *et al.* (2008a,b) on the basis of a field experiment with light petroleum compounds in the unsaturated groundwater zone (Fig. 3–12). Further, it has been shown by Tyler *et al.* (1994) that the rate of aerobic methane oxidation (MO) in temperate soils is largely controlled by the rate of diffusive methane influx, implying a likewise balanced biodegradation-*vs*.-charge hydrocarbon turnover.

Compositional biodegradation fingerprints It becomes more and more clear that diffusive segregation of hydrocarbons within the deep biosphere is strongly coupled to and largely controlled by microbial alteration as the incompatibility between free gas transport and microbial accessibility has repeatedly been suggested by various field studies, *e.g.* in case of ebullitive gas transport through the aerobic zone of shallow marine sediments (Grant & Whiticar 2002) or as the cause for steepened hydrocarbon (nutrient) concentration gradients down towards the base of commercial petroleum accumulations (Jones *et al.* 2008).

The implied coupling between microbial overprints and a diffusive hydrocarbon migration mechanism allows a quantification of the extent to which the sampled gas has been exposed to microbial wet gas degradation in order to unravel the migration history of borehole gas profiles. It has been demonstrated that wet gas carbon isotopes may indicate excessive unbalances between microbial generation and consumption processes (*e.g.* Fig. 3–7a). However, the comparatively vague isotopic shifts that are allocated to quasi-balanced methanogenic biodegradation (*e.g.* Figs. 3–7b and 3–11) must be emphasised by molecular compositional proxies that reflect the temperature trends in Figures 3–9 and 3–10. A first step towards this goal is the determination of pristine wet gas compositions of the original thermogenic and microbial end-members.

Since the microbial production of propane (and presumably higher hydrocarbons) has only recently been discovered (Hinrichs *et al.* 2006) the ethane fraction in a binary methane-ethane system C2/(C2+C1) is considered the best indicator for the extent of biodegradation. The pristine thermogenic ethane concentration can be deduced from a linear extrapolation of the wettest gas samples towards the thermogenic isotope fingerprint (Fig. 3–13) because these gases are most likely to represent an advective transition between the two genetic gas end-members. The linear nature of the trendline in 3–13 is in agreement with the models of Prinzhofer & Pernaton (1997; see Fig. 2–7). The resulting ~11 vol.% $C2_t$ as an average composition of unaltered pristine thermogenic hydrocarbons agrees with gas data sampled from the abiogenic zone of the sub-Messinian stratigraphy

(unpublished data courtesy of T. Dodd personal communication).

Determination of the missing or depleted ethane content $C2_x/(C2_x+C1)$ – *i.e.* the relative ethane fraction x that has been removed from the system by processes such as biodegradation – is a straight forward procedure under consideration of mass balance between the binary mixtures of microbial gas ($C1_m+C2_m$) and thermogenic gas ($C1_t+C2_t$) that are exposed to wet gas depletion ($C2_x$):

$$C1\ [vol.\%] = C1_m + C1_t \qquad (3c)$$

$$C2\ [vol.\%] = C2_m + C2_t - C2_x \qquad (3d)$$

The compositional ethane end-members as a fraction of microbial and thermogenic methane content are expressed as follows:

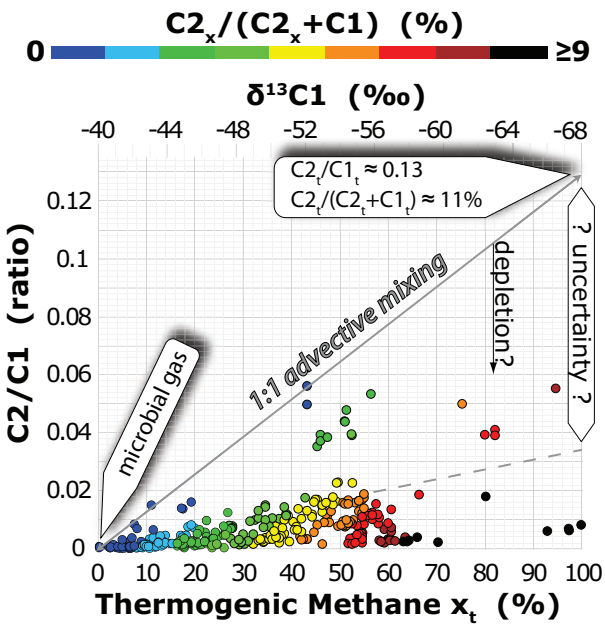

Figure 3–13 Extrapolation of the unaltered advective gas mixture yields the pristine thermogenic ethane composition $C2_t/(C2_t+C1)$ = 11% that allows the determination of the missing or depleted wet gas $C2_x/(C2_x+C1)$ (Equ. 3h; see text for uncertainties). The linear nature of the mixing trendline is in agreement with the models of Prinzhofer & Pernaton (1997; see Chapter 2.3).

$$C2_m\ [vol.\%] = 0.0005 \cdot C1_m \qquad (3e)$$

$$C2_t\ [vol.\%] = 0.11 \cdot C1_t \qquad (3f)$$

Equations 3e and 3f yield the expected maximum ethane composition $C2_{max}/(C2_{max}+C1)$ for each sample as a function of its individual gas genetic fingerprint:

$$C2_{max}/(C2_{max}+C1)\ [frac] = (C2_m + C2_t) / 100 \qquad (3g)$$

This relation allows an estimate for the extent of ethane depletion $C2_x/(C2_x+C1)$ in the binary methane-ethane system:

$$C2_x/(C2_x+C1)\ [frac] = C2_{max}/(C2_{max}+C1) - C2/(C1+C2) \qquad (3h)$$

On the basis of this simple end-member calculation the theoretically or apparently missing ethane concentration from Equation 3h (see also colour-code in Fig. 3–13) would be expected to illustrate the influence of biodegradation on the primary genetic isotope mixing between the species involved. However, the biodegradation pattern in Figure 3–14 is inconsistent with the expectations because a depletion of molecular C2 that is coupled to increasing thermogenic isotope signature seems unlikely. The conclusions drawn from this theoretical experiment are that either (1) most of the thermogenic gas that arrives in the Plio-/Pleistocene deep biosphere is already depleted in wet gas by an unknown proc-

ess or (b) the thermogenic ethane compositional end-member of ~11% is not consistent throughout the case study but rather refers to the most immature hydrocarbons that were analysed.

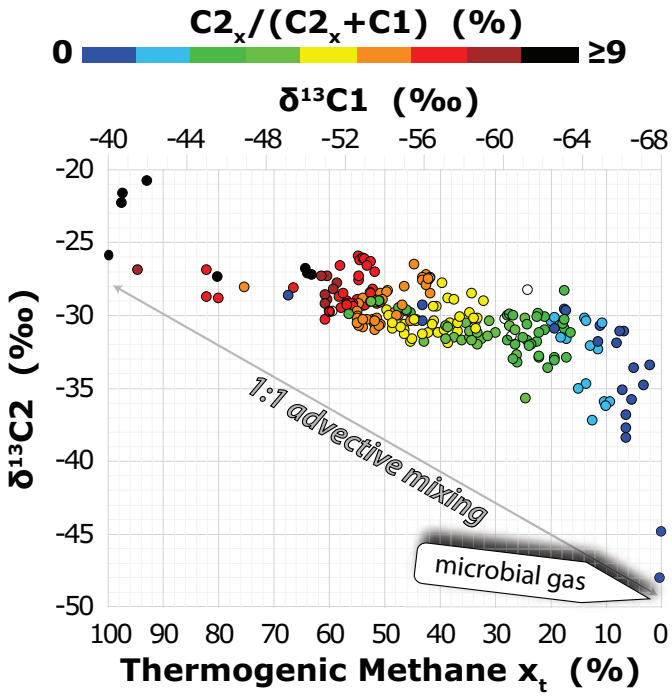

Figure 3–14 Evidence of variations in the natural ethane content of thermogenic gas. The allocation of 11% ethane to the pristine thermogenic gas end-member appears to be invalid because the hereby calculated missing or depleted ethane concentration $C2_x/(C2_x+C1)$ from Equation 3h is unlikely to be a function of thermogenic gas fraction. In contrast, the $\delta^{13}C1$-based model for gas genetic mixtures is confirmed by the convergence of the data scatter towards the pristine $\delta^{13}C2_t$ fingerprint from the sub-Messinian gases ($\delta^{13}C2_t \approx$ -28.5‰). See text for nature of data deviation from the theoretical 1:1 advective mixing line.

A more conclusive feature of Figure 3–14 is the power law curvature of the gas genetic mixing trend. A possible explanation would be that lower diffusivities of C2 relative to C1 molecules lead to an unbalanced or differential $\delta^{13}C2$ *vs.* $\delta^{13}C1$ isotope shift (*e.g.* Zhang & Krooss 2001), *i.e.* the entire petroleum system has a gas geochemical overprint from diffusive migration. However, these considerations neglect the differences in initial ethane compositions of the thermogenic and microbial gas end-members. Even if the admixing thermogenic ethane concentration varies between roughly 3-11% (Fig. 3–13) the most methane rich thermogenic injection into the methanogenic zone of the deep biosphere has a 40-fold higher ethane content as *in situ* microbial gas ($C2_m$ = 0.05%). Consequently, the migrating thermogenic gas must be exposed to a significant extent of dilution by its microbial counterpart before the light $\delta^{13}C2_m$ has a noticeable effect on the bulk isotope ratio of the gas mixture.

For example, a 1:1 admixture of gas with 2% thermogenic C2 ($\delta^{13}C2_t$ = -28.5 ‰) and 0.05% microbial C2 ($\delta^{13}C2_m$= -48 ‰) will result in a bulk carbon isotope fingerprint of -29.0 ‰, *i.e.* the microbial effect in this conservative calculation is already close to the order of the isotope measurement error (~0.1 ‰). A linear $\delta^{13}C2$ *vs.* $\delta^{13}C1$ transition between the two genetic gas types would therefore be expected only if they had the same ethane concentration (grey line in Fig. 3–14) given that gas mixing by advective flow itself has no superimposing segregative isotope effect (*e.g.* Zhang & Krooss 2001, Bouchard *et al.* 2008a,b; see Chapter 2.3).

Migration fingerprints It is understood that a quantitative biodegradation model that is based on molecular C2 end-member calculations (Equs. 3e-h) shows no causal validity in terms of their isotopic equivalents (Fig. 3–14) due to a natural variation in both primary microbial and thermogenic C2 generation.

In an alternative approach, re-evaluation of the previous wet gas depletion study by relating the measured molecular C2 concentration to the modelled thermogenic $C1_t$ concentration (Equ. 3b) is found to yield a more rigid proxy for biodegradation (Fig. 3–15a): wettest samples are associated with the lightest $\delta^{13}C2$ if more than ~30% thermogenic gas is involved. Ethane isotopes of this non-degraded mixing trend are only affected beyond 90% microbial gas contamination (x_t<10%) which is in agreement with the previous argumentation: mixing of genetic end-members with unequal molecular ethane fraction will deviate from a 1:1 mixing line (Fig. 3–14).

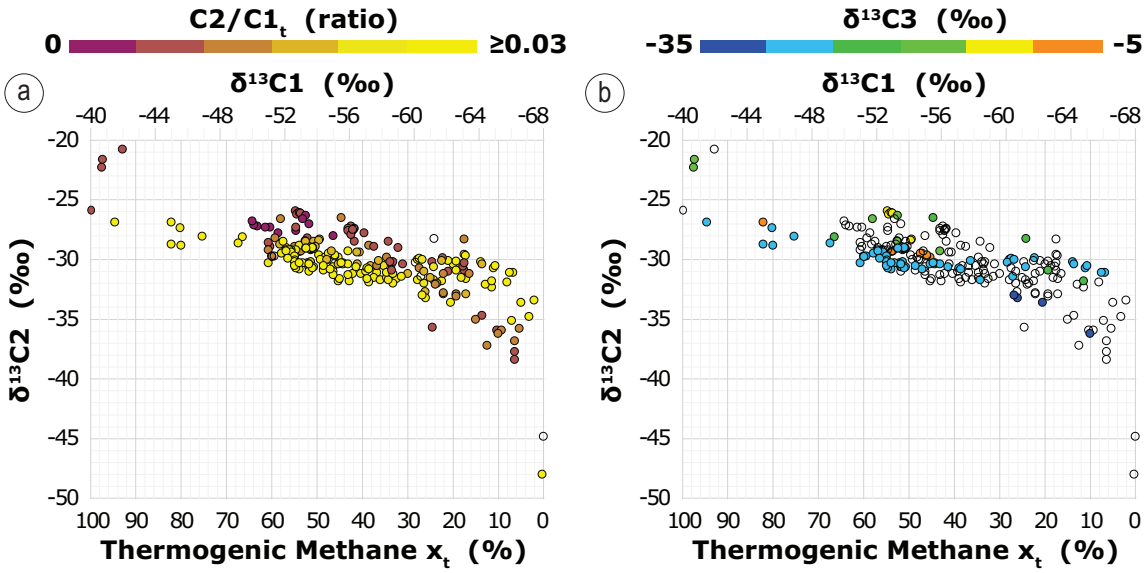

Figure 3–15 Both (a) modelled thermogenic gas ratios and (b) measured propane carbon isotopic ratios support a discrimination between methanogenic biodegradation effects and largely unaltered mixing between the two primary gas genetic end-members. Very heavy $\delta^{13}C3$ between the two trends (orange points in b) imply unbalanced biodegradation imprints during migration across the gas-water contact (GWC) of hydrocarbon accumulations.

It is understood that $\delta^{13}C3$ of this proposed quasi-linear mixing trend is not visibly affected (Fig. 3–15b) because biodegraders cannot access a migrating free gas phase (Chanton *et al.* 1992, Grant & Whiticar 2002), *i.e.* both linearity and lack of biodegradation indicate an advective flow system for the gas samples that plot in the vicinity of this trendline (dashed in Fig. 3–16a).

In contrast, the compositionally dry thermogenic gas trend (low $C2/C1_t$ ratios) in Figure 3–15a complies with the features of (1) biodegraded gas (relatively heavy $\delta^{13}C2$ and $\delta^{13}C3$ above 30% thermogenic gas content) on the one hand and (2) strong imprints of microbial gas generation (exceptionally light $\delta^{13}C2$ and $\delta^{13}C3$ below 30% thermogenic gas content; see also Fig. 3–15b) on the other hand. It is therefore proposed that this "dry"

trend is controlled by metabolic mediation of syntrophic microbial communities that require a diffusive environment (pink line in Fig. 3–16a). The methanogenic isotope fingerprint dominates below 30% thermogenic gas contamination presumably because wet gas biodegraders lack nutrient supply and may fall dormant, starve, or never even colonised the associated stratigraphy. This diffusive microbial equilibrium is considered responsible for the rough temperature stratification in the hydrocarbon concentration ratios as presented earlier (Figs. 3–9 and 3–10) while the "wet" advective trend accounts for deviations from such diffusively equilibrated conditions.

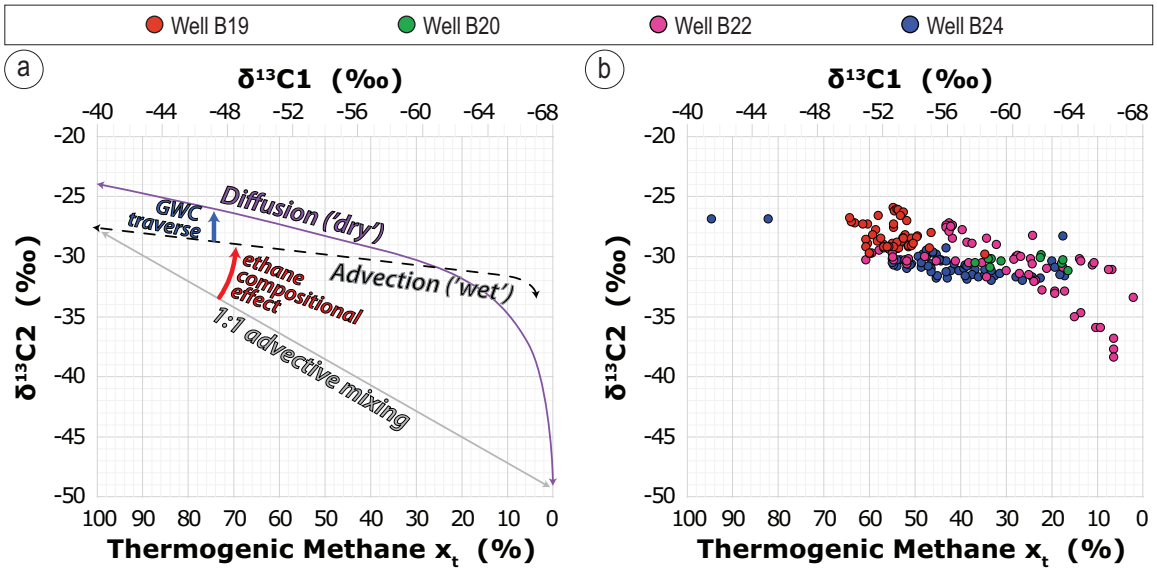

Figure 3–16 (a) Interpretation of the distinct trend lines in the previous figures ("wet" vs. "dry" gas composiitons) on the basis of microbial inaccessibility to free gas phases and the reasoning of Prinzhofer & Pernaton (1997; see Chapter 2.3). Deviation of the actual advective mixing line (dashed) from the hypothetical 1:1 advective mixing trend is due to inferior ethane concentrations of the microbial gas end-member (see text). Note that the microbially mediated crossing of the gas-water contact (GWC traverse, blue arrow) has a unidirectional impact on gas chemistry because advective flow does not overprint such inheritant diffusion and (unbalanced) biodegradation fingerprints (see text). (b) Undistinguished gas samples from the four priority wells (see text for discussion).

It is possible to annotate the apparent advection and diffusion trends to the measured data under the reasonable assumption that the net migration pathway of the thermogenic fraction is directed towards the sediment interface at the Mediterranean sea bottom. However, it must be noted that the diffusive/microbial imprint on the gas data is a unidirectional phenomenon that may only be reset by advective dilution with unaltered gases (see caption of Fig. 3–16a).

Alternative interpretation It should be mentioned that there is at least one reasonable anti-hypothesis for parts of the aforementioned argumentation. The steep inclination of the previously identified diffusion trend towards the microbial isotope fingerprint (below 20% thermogenic methane in Fig. 3–16a) could as well be an artefact of advective mixing between primary microbial gas and secondary dry thermogenic gas that was previously biodegraded exclusively at the GWC. Stripping off most of the C2+ components at the

base of accumulations produces a new mixing end-member for microbially generated gas that is in compositional alignment. Hence, advection between biodegraded thermogenic gas and pristine methanogenic gas would be expressed by a straight line in the $\delta^{13}C1$ *vs.* $\delta^{13}C2$ with a similar slope as the 1:1 advective mixing line (Fig. 3–17a).

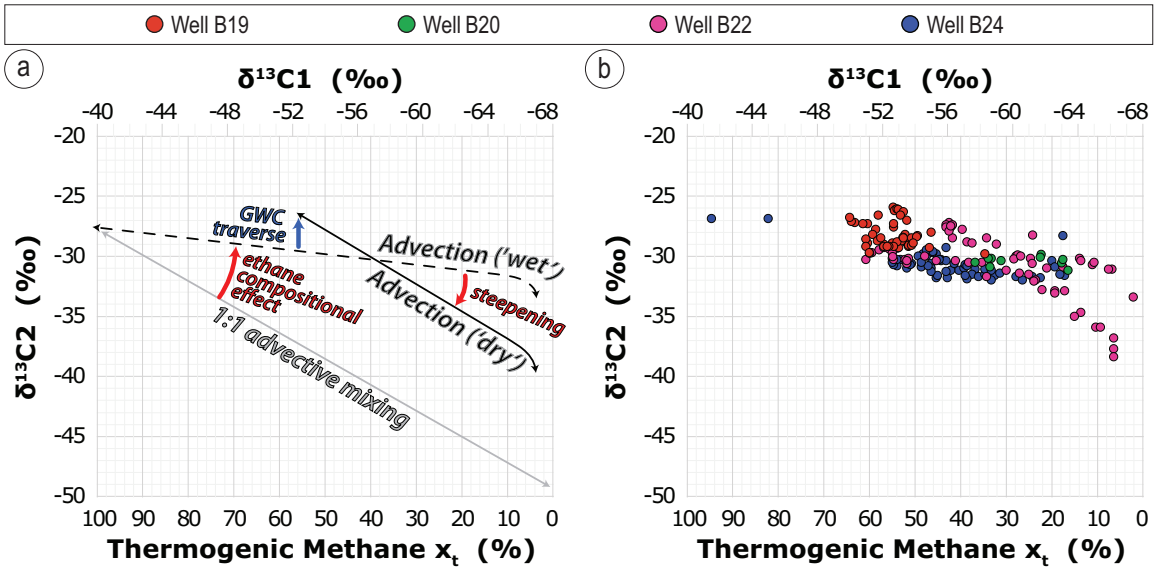

Figure 3–17 (a) Alternative interpretation of the characteristic "dry" mixing trend in Figure 3–15a. Molecular ethane depletion by exclusive wet gas biodegradation at the gas-water contact (GWC) would introduce a steepening of the unaltered ("wet") advective mixing trend (downwards-directed red arrow). The schematic Figure examplifies a mixing trend that has a similar slope as the hypothetical 1:1 advective mixing line (grey), *i.e.* in this example biodegraded ethane concentrations would have a similarly low magnitude as the microbial ethane biproduct. (b) Undistinguished gas samples from the four priority wells (see text for discussion).

Likewise, this alternative scenario would yield an explanation why the lightest $\delta^{13}C3$ data points (dark blue dots in Fig. 3–15) plot on such steep advective trend: the trace concentrations of isotopically light microbial propane ($C3_m$) have a perceivable impact on the admixed $\delta^{13}C3$ ratio because the biodegraded mixing partner is comprehensively depleted in thermogenic propane ($C3_t$). However, such considerations about the secondary evolution of C3 isotope ratios would also comply with the diffusive-methanogenic-biodegradation scenario that was outlined in Figure 3–16a.

The skewed isotope mixing effect between gas genetic end-members of differing hydrocarbon composition can be demonstrated by the application of a simple advective mixing model (Equs. 3i-k).

$$\delta^{13}C1_{mix}\ [‰] = \delta^{13}C1_m - C1_t / (C1_t + C1_m) \cdot (\delta^{13}C1_m - \delta^{13}C1_t) \quad \textit{(3i)}$$

$$\delta^{13}C2_{mix-t}\ [‰] = \delta^{13}C2_m - C2_t / (C2_t + C2_m) \cdot (\delta^{13}C2_m - \delta^{13}C2_t) \quad \textit{(3j)}$$

$$\delta^{13}C2_{mix-d}\ [‰] = \delta^{13}C2_m - C2_d / (C2_d + C2_m) \cdot (\delta^{13}C2_m - \delta^{13}C2_d) \quad \textit{(3k)}$$

Such hypothetical ("ideal") mixing trendlines between (1) thermogenic gas *vs.* microbial gas mixing and (2) C2-biodegraded gas *vs.* microbial gas mixing can be fit to the measured $\delta^{13}C1$ *vs.* $\delta^{13}C2$ data points by systematic trial-and-error modification of the

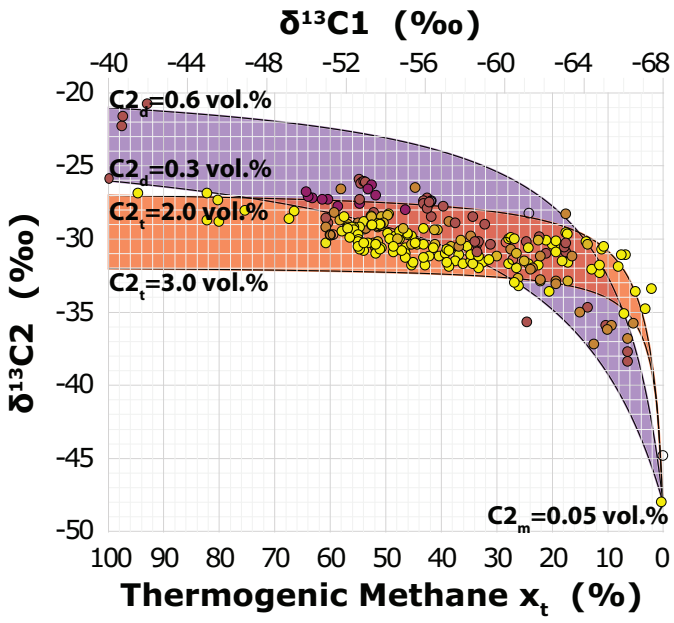

Figure 3–18 Example fit between simple advective mixing model trendlines (Equs. 3i-k) and measured carbon isotope data from the Nile Delta. The pink area represents the range of the biodegraded-vs.-microbial gas mixing and the red area refers to the thermogenic-vs.-microbial gas system.

proposed end-member fingerprint (Fig. 3–18).

Certainly, discrimination between the "wet" advective mixing trend of pristine genetic end-members and the ominous "dry" mixing trend is vital for the interpretation of the hydrocarbon migration history along gas-sampled borehole intervals. In terms of the data priority wells from the two case studies (Chapter 1.2), gas samples from Wells B20 and B24 plot mostly on the "wet" advective trendline (Figs. 3–16b and 3–17b). In contrast, B19 and B22 exhibit alternating "dry" diffusive/advective and "wet" advective elements with either constant gas genetic mixture at various unbalanced biodegradation stages (B19) or strong mixing gradients (B22).

However, allocation of the suffix "advection" or "diffusion" to the "dry" mixing line must be accomplished in the context of both lithology (Part II) and relative volumetrics of free gas and brine in the pore space (Part III). An elaboration on the spatial distribution of gas-geochemical migration indicators along the borehole profiles will be a major contribution to the synthesis in Part IV of this thesis.

Synopsis of Chapter 3 Unravelling natural gas migration mechanisms and pathways in the Pliocene strata of the western Nile Delta fan is a major challenge due to the ubiquitous occurrence of locally generated microbial gas (~99.7% methane, C1). The arrival of thermogenic gas (>90% C1) from a deep source rock results in gases which generally contain >98% C1. In addition, there is evidence for combined methanogenesis (light $\delta^{13}C1$, heavy $\delta^{13}C_{CO2}$) and wet gas biodegradation (C2+ depletion).

Both mixing effects and microbial recycling severely restrict the application of classic carbon isotope models for thermogenic gas maturity assessment (*e.g.* James 1983, Clayton 1991, Berner & Faber 1996). However, the apparent absence of isotope effects that are associated with anaerobic oxidation of methane (AOM) allows a rough partition of the hydrocarbon gas mixture into its genetic components by a coupled methane isotope-

and-concentration end-member model. Variations in thereby isolated thermogenic gas properties relate to formation temperature and result from biodegradation rather than maturity.

Ethane carbon isotopic biodegradation fingerprints (abnormally heavy $\delta^{13}C2$) are largely concealed by the co-production of isotopically light microbial ethane, introducing the term *quasi-balanced* methanogenic biodegradation. Further, the causal link between a herein proposed discrimination of "dry" diffusive from "wet" advective gas genetic mixing trends in the combined analysis of methane and ethane compositional and isotopic data is based on (1) various literature reports that microbial attack on free gas phases is hindered by restricted physical access and (2) segregative isotope fractionation as a consequence of differences in methane and ethane diffusivity (Prinzhofer & Pernaton 1997; see Fig. 2–7).

These findings support the idea of a widely present coupling between both methanogenic and biodegrading microbial communities. These exhibit strong carbon isotopic disbalances at gas-water contacts (GWC) where nutrient supply is in favour of the biodegrading metabolism. However, extensive wet gas depletion from microbial activity at the GWC produces a secondary "dry" thermogenic mixing end-member that may steepen the advective mixing trendline (see Fig. 3–17) and thereby mimic the "dry" diffusive migration fingerprint (see Fig. 3–16). Consequently, the hypothesis of coupled diffusive/microbial gas overprints must be tested in the context of lithological profiles (Part II) as well as pore fluid saturations (Part III) in Part IV of this thesis.

It is concluded that an adequate quantification of the abnormally "dry" gas mixing trendline in Figures 3–16 and 3–17 will help to identify stratigraphic intervals that are hardly affected by advective leakage through the pore space and are therefore bypassed (Chapter 8).

Part II – Lithological Context

Setting the gas geochemical implications from the previous chapter into an adequate lithological context is not a straight forward task.

Ideally, each observed combination of wireline log signals represents a unique interference of lithology/fluid properties within the detected formation volume. However, gas geochemical data cannot be plotted against such petrophysical information due to a variety of issues concerning scale, resolution, and coherency of measurement depth (Chapter 1).

Instead, the primary aim of Part II is to simplify the unique log signal combinations into a representative set of not more than 13 clearly distinct units. The results of the core sample analyses (Chapter 4) will be used to calibrate manual (*i.e.* subjective) lithofacies interpretation from core images (Chapter 5.1) that serve as the basic framework for automated wireline facies recognition and propagation (Chaper 5.2).

Apart from detailed and consistent geological profiles that provide the context for the gas migration analysis (Part IV) a secondary aim of Part II is the calibration of raw wireline log signals through upscaling of laboratory rock properties.

Chapter 4 Grains and pores at the sample scale

With the ambition of adding up the established BP data set on properties of more than 300 cap rock samples from a total of 19 western Nile Delta fan wells, new analysis were produced on 92 virgin samples from nine of the mentioned wells. As the sampling rationale aimed at fluid retention capacities only the tightest lithologies of the local Plio-/Pleistocene petroleum systems were recovered for property characterisation, namely clay-rich argillaceous rock samples or mudstones.

The sample set comprises – with two exceptions – plugs, drilled from the split core, labelled with information about well name, sample number, and true vertical depth (TVD). The sample set from BP Egypt, Cairo, was received at Newcastle University by end of January 2008. A well-by-well overview of the rock data set is given in Figure 1–5 whereas the full database is presented in Appendix C.

4.1 Grain size distributions

Siliciclastic sediments are usually categorised by their predominant mineralogy and grain size fraction (Füchtbauer 1988, Potter 2005). Yang & Aplin (1998) were the first authors to proof that the link between clay-sized particles (<2 µm) and clay mineral content is sufficiently strong for the utilisation of argillaceous particle fractions as a standalone lithology proxy in mudstone permeability studies. This chapter reports on the analysis and range of grain size distributions among the 92 mudrock core samples.

Sample preparation Examination of the grains that comprise a lithified sediment inevitably requires their isolation from the rock matrix prior to measurement. In this study, the Saturation-Freeze-Thaw (SFT) technique from Yang & Aplin (1997) was chosen because it has been proven to recover the original grain size distribution with the least possible corruption from broken grains. The disaggregation method is described in the following paragraphs.

A minimum of 2 grams of fragments per sample – a few millimetres in diameter (Fig.

Figure 4–1 Grain size sample (a) prior to disintegration, (b) after disintegration, and (c) re-moistened prior to final dilution.

4–1a) – were placed in labelled aluminium tins and covered with deionised water. Subsequent vacuum dessication (~1h) supported the water percolation into the pore space of the aggregated sample fragments. Transfer of the saturated samples into a conventional freezer (~2h at -20°C) lead to gentle weakening of the inner rock friction through steady pore water expansion before oven-thawing (~1h at 85°C) reset the samples for the next SFT-cycle (Fig. 4–1b). Disaggregation states were visually examined between the loops and repetition lasted until each rock sample was transformed into soft mud (Fig. 4–1c). Up to 10 cycles are commonly enough to obtain poorly aggregated fragments below 2 mm (Yang & Aplin 1997) of which 1.00 ± 0.05 g (dry weight) were extracted for completion. At this stage it is important to record the exact weight of each sub-sample for later determination of the sand fraction (>63 µm).

Finally, about half a minute ultrasonic probing in 20 ml of deionised water accomplished dispersion of the loose grain aggregates. Coagulation of released clay minerals was prevented by a chemical dispersant (0.05 mol% $[NaPO_3]_6$ in 50 ml sample emulsion).

Methodology: Sedigraph The grain size analysis was conducted via automated laser detection (SediGraph 5000ET, Micromeritics; Fig. 4–2). Before each measurement, the machine runs with a dispersant blank (0.05 mol% $[NaPO_3]_6$) in order to set a steady baseline at 0% cumulative grain fraction. The first two sample beakers were put into the chamber of the sedigraph and left there for about an hour to establish the operating temperature of 28-35 °C.

Figure 4–2 Front panel of SediGraph 5000ET (Micromeritics).

Once set, the machine's tubing loop was cautiously loaded with a sample dispersion and trapped air bubbles released. An integrated pump ensures the continuous connection between the sample beaker and the measuring cell. Measurement starts as the pump stops and the dispersion inside the cell commences to settle. Referring to Stokes' Law, we find that the equivalent spherical diameter D (m) of a given grain is proportional to its settling velocity v (m/s):

$$D^2\,[m] = 18 \cdot \eta \cdot v \cdot \{(\rho - \rho_o) \cdot g\}^{-1} \qquad \textbf{(4a)}$$

where η is the viscosity (kg/m/s) of

the liquid, (ρ–ρ_O) is the density difference (kg/m^3) between the grain material and the liquid, and g is the standard gravity (m/s^2). However, the range of analysed grain sizes is too large to measure the settling velocity over a unit distance within reasonable time periods for practical purposes. The device overcomes this problem by a digital controller that moves the measurement cell downward relative to the detecting X-ray beam, *i.e.* the distance over which the settling rate is measured is continuously shortened as the particle size inside the cell decreases upwards. The functions of the instrument are such that the cell's lowering rate v_r is determined from the following equation:

$$v_r\,[m/s] = 211.80[m/s^2]\cdot(\rho-\rho_O)\cdot\{50/D_m)^2\cdot\eta\}^{-1} \qquad \textbf{(4b)}$$

where D_m is the maximum particle diameter to measure (63 µm). The rate units are practically irrelevant because the machine converts them internally into appropriate speed and acceleration. Temperature dependent parameters such as viscosity (η) and density (ρ) were set prior to each measurement.

As the beam scans the cell from bottom to top of the dispersion the measured grain fraction starts at the coarse end (63 µm) and subsequently moves towards the finer grains (≥ 2.5 µm) near the top of the dispersion. The particle concentration at the level of the cell that intercepts the collimated X-ray beam is processed by an internal scintillation detector into a directly proportional net output signal. The real-time corresponding particle size is indicated by the logarithmic signal of yet another digital controller that enables a Stokes' Law-conform plot of the output signal on a logarithmic cumulative grain size paper chart.

Data processing & results Since the SediGraph records only the ≤ 63 µm fraction the machine's output data required manual correction for the sand fraction. This was achieved from relating the weight of particles recovered in a 63 µm mesh sieve to the initial dry sample weight. Further, the corrected data was converted by a machine-specific empirical formula that fits the grain size distribution expected from the pipette method – which is herein considered as the default sedimentation procedure. Repeated analysis of 10 samples yield a measurement error of ±0.55%.

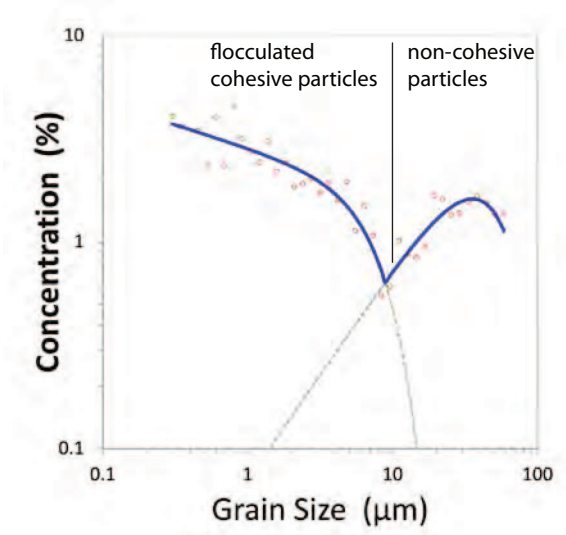

Figure 4–3 Regression of a measured grain size distribution (Well B20, sample 35). Floc (left) and clastic (right) regressions intersect at about 10 µm which is equivalent to the coarse silt-to-cohesive silt discrimination.

In order to emphasise global trends in the 92 grain size data sets a regression of the scatter has been performed according

to Kranck *et al.* (1996a,b, see Fig. 4–3). Their method involves individual curve-fitting to both clastic fraction (sand+coarse silt) and flocculation tail (cohesive silt+clay) of a mudrock and is particularly useful for dicriminating different sediment classes on the grain size scale. The regression parameters as well as clastic/floc intersect have been further processed in a simple hierarchical cluster analysis according to the single-linkage method. In short, after standardisation to a mean of 0 and a standard deviation of 1 the Euklidic distance between each sample is determined; couples with the least distance are subsequently grouped in order of their common distance.

The method strictly resulted in 19 different distributions which were broken down into 3 characteristic patterns that may shift along the x-axis (Figure 4–4). In general, the deeper the depression between the two peaks the clearer the separation between flocculated clay/cohesive silt particles on one hand and non-cohesive grains (coarse silt + sand) on the other. This characteristic coarse silt-to-cohesive silt separation at approximately 10 µm has no effect on the net concentrations of the 4-fold grain size pies (see inlets of

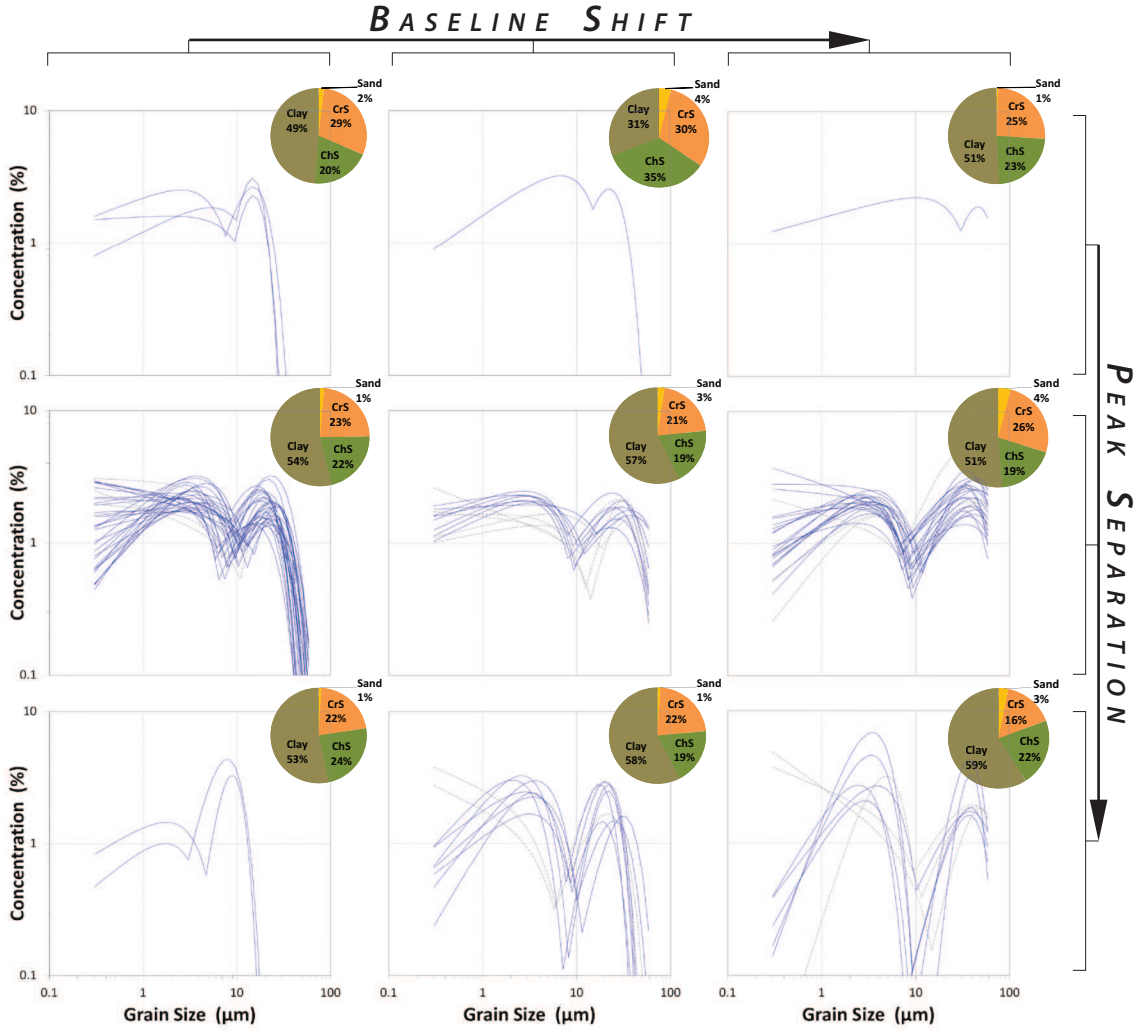

Figure 4–4 Characteristic grain size distributions of the 92 measured mudstone samples. The results are grouped according to peak emphasis and demonstrate a general tendency for baseline shift of the non-cohesive particle peak. A genetic effect is not, however, reflected in the 4-fold grain size pies (inlets: average per group). See text for further discussion. CrS: coarse silt; ChS: cohesive silt.

Fig. 4–4). The general variability within the example distributions of Figure 4–4 is subject to sediment provenance, depositional energy, and occurrence of mechanical reworking events prior to burial (Kranck *et al.* 1996b). As sediment genesis is largely covered by lithofacies interpretation on the core image scale in Chapter 5.1 it is beyond the scope of this project to perform a sample-scale facies characterisation. Instead, further processing of sand and especially clay content as lithological proxies is presented in Chapter 5.

4.2 Porosity

In geosciences, physical or total porosity refers to the formation volume that is not occupied by mineral grains whereas effective porosity relates to the voids in soils or rock that contribute to fluid transport (Pearson 1999, Sevee 2010). The handling of these two fundamental porosity types in the context of fluid migration is further discussed in Chapter 7.2. Mercury injection porosimetry captures the distribution of a sample's total porosity if pore radii exceed approximately 2 nm.

Sample preparation A minimum of 2 grams of appropriate sample fragments (max. 5*15 mm; Fig. 4–5) were picked from the shards of the broken-up plug and transferred into labelled vials. A ModuloyD Freeze Dryer (Thermo Electron Corporation) cooled the uncovered samples down (2h at -50°C) before the onset of a vacuum initiated a 24h sublimation period, *i.e.* the frozen pore water was transformed directly into the gas phase as a result of pressure reduction, leaving behind a dried sample. This procedure is preferred relative to direct heating of unfrozen samples since the former is meant to have less effect on the water within hydrated minerals (especially in smectites, which are common in the analysed samples). Processed samples were stored at 80°C prior to measurement in order to maintain their dryness.

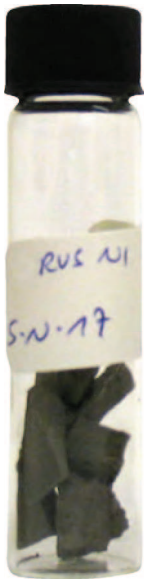

Figure 4–5 MIP samples.

Methodology: Mercury injection porosimetry (MIP) About 1.5 g of sample chunks are transferred into an empty penetrometer that consists of an about 30cm long glass tube attached to a sample compartment of known volume. The compartment is grease-sealed with a metal connecting plate. The equipped penetrometer is subsequently tightened up in one of the pressure ports and measurement can proceed.

The MIP instrument consists of two different pressurised parts: (1) four low-pressure (LP) ports up to 25 psia and (2) two high-pressure (HP) ports up to 40,000 psia (Fig. 4–6).

While LP precedes HP measurement both steps follow the same principle: the vacuum cells fill with mercury and pressure increases in 30-40 different increments, each of which corresponds to a particular pore diameter. The volume of the intruded mercury at each step is deduced from the current electrical capacity. Typical periods of equilibration may stretch a single run to a little more than one hour.

Figure 4–6 MIP instrument Autopore II 9220 (Micromeritics) with 4 low-pressure ports (top) and 2 high-pressure ports (base).

Data processing & results The following weights were recorded at different stages during the preparation process: empty penetrometer, sample-equipped penetrometer prior to measurement, and mercury saturated penetrometer after measurement. These records were required to calculate dry sample weight, saturated mercury weight, and mercury volume prior to initial pressure build-up. Further data processing in conjunction with the associated sample grain density (see Appendix B.1) yield the rock matrix volume, and the mercury density at the recorded ambient temperature yields the saturated mercury volume, *i.e.* the total sample porosity that was intruded by mercury. Repeated analysis of 10 samples yield a measurement error of ±0.47% which is similar to the sedigraph accuracy (Chapter 4.1).

Results were plotted in diagrams that show the distribution of incremental and cumulative porosity as a function of pore diameter. The incremental porosity usually tails off towards the largest pore sizes. However, if the smooth decline disturbed by abrupt and slightly scattered porosity rise it is very likely that micro-cracks – initiated upon core recovery – are present and filled at low mercury injection pressures (Fig. 4–7). In this case the application of cut-off pore radii is considered a valid procedure to conserve data output quality. Accordingly, where cut-offs have been used a correction for the initially calculated total porosity is necessary.

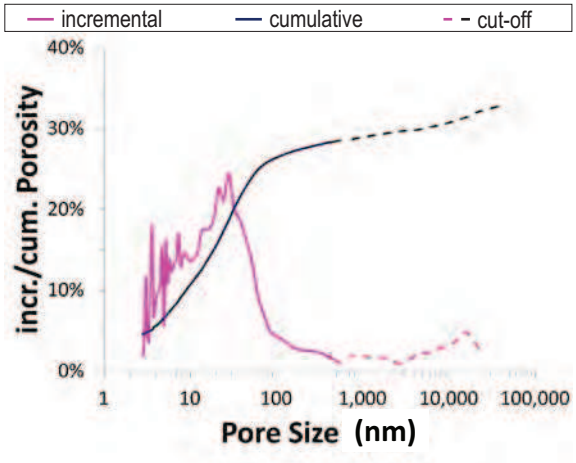

Figure 4–7 Typical pore size distribution of a fine-grained sediment with cut-off porosity at large pore diameters (low mercury injection pressures). Example from Well B24, sample 8.

The resulting pore size distributions of the bulk sample set were grouped according to curve shape. Five typical distributions are discriminated of which 4 are unimodal (Fig. 4–8) and one bimodal (Fig. 4–9).

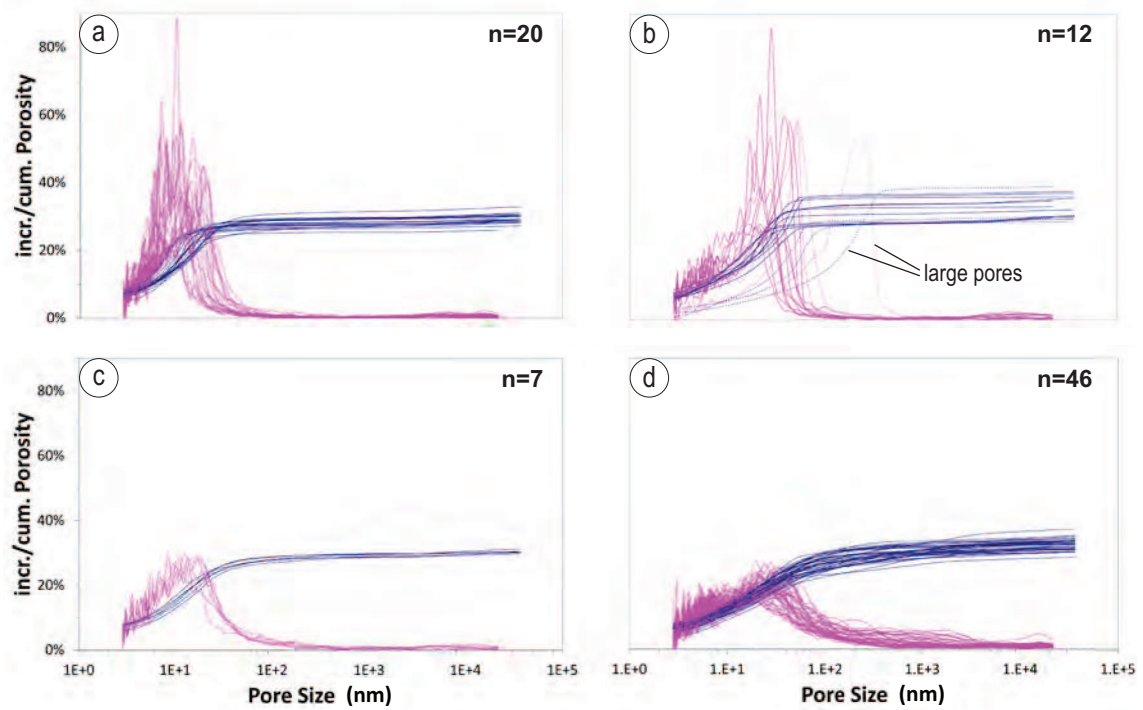

Figure 4–8 Four major groups of pore size distributions from 92 core samples. (a-b) Narrow pore size range restricted to (a) relatively smaller pores and (b) relatively larger pores. (c-d) Likewise, broader spectrum with pores clustering around (c) relatively smaller pores and (d) relatively larger pores. Those samples that do not fit in these categories have a bimodal distribution (see Fig. 4–9).

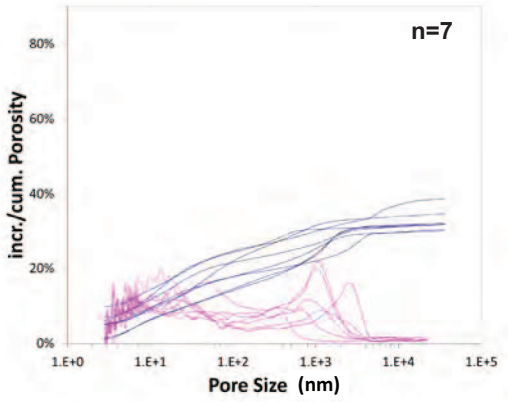

Figure 4–9 Bimodal pore size distributions imply thin laminae.

Experimental work from Schowalter (1979) has lead to the widely acknowledged assumption that the pore radius at 10% mercury saturation (r_{10}) is a good estimate for the minimum pore size required to connect a continuous filament of non-wetting phase throughout a porous medium such as a mudstone cap rock (*e.g.* Nabawy *et al.* 2009 – and references therein). In other words, an average saturation of 10% non-wetting phase (*e.g.* mercury or hydrocarbons) is required to overcome the percolation or displacement threshold of a pressure seal and thus initiates capillary failure or leakage (see Chapter 6). The pressure at 10% saturation is the displacement pressure necessary to overcome the capillary pressure at the associated pore size.

Since the physical properties of hydrocarbons significantly deviate from those of mercury a modified Young-Laplace equation is required to translate into the equivalent hydrocarbon pressure (Equ. 4c). This equation is also known as Washburn equation

(Washburn 1921, Purcell 1949, Lowell & Shields 1991).

$$P_c\,[Pa] = P_{nw} - P_w$$
$$= (\rho_{nw} - \rho_w)\cdot g\cdot h$$
$$= 2\sigma / r_{10}\cdot cos\theta \qquad \textit{(4c)}^1$$

Rearrangement of this equation yields the potential hydrocarbon column height (Fig. 4–10). However, these relations only exist if there is on average less than 10% of free non-wetting phase present in the pore space of a cap rock. Once capillary failure has occurred and the cap rock is breached, migration along continuous filaments will be a function of relative permeability and the potential column heights estimated above become unrealistic.

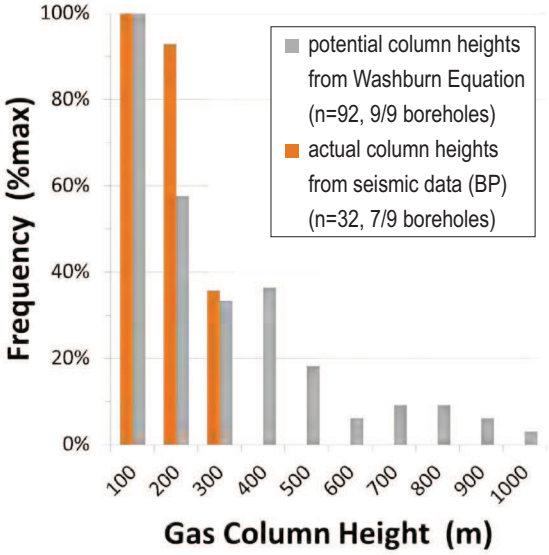

Figure 4–10 The comparison of potential and actual gas column height distributions (BP data) from the sampled boreholes implies that calculations based entirely on capillary entry pressure may result in severe overestimations if charge and trap configuration are not limiting factors. Frequencies are normalised by maximum sample number.

Permeabilities can be estimated via empirical formulas from parameters such as clay content and mean pore radius (Yang & Aplin 1998 & 2004) or total porosity (Yang & Aplin 2010). Further, anisotropies that result from mechanical compaction during burial can be estimated from empirical correlations with clay content and effective stress (Yang & Aplin 1998), enabling the discrimination between vertical permeability (K_v) and horizontal permeability (K_h). Results for the 92 mudstone samples span several orders of magnitude depending on method and spatial orientation (Fig. 4–11).

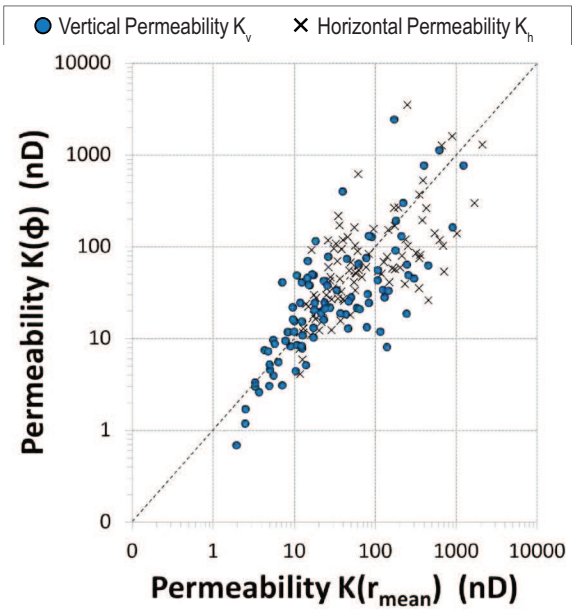

Figure 4–11 Modelled permeabilities from empirical correlations based on clay content and mean pore radius (r_{mean}; Yang & Aplin 1998 & 2004) and total porosity (φ; Yang & Aplin 2010) indicate a large magnitude range.

The model based on mean pore radius (x-axis in Fig. 4–11) is physically more constrained than the total porosity-related model (y-axis in Fig. 4–11) because it considers a representative parameter from the

1 P_c [Pa] – capillary entry pressure; P_{nw} [Pa] – pressure of non-wetting phase; P_w [Pa] – pressure of wetting phase; ρ_{nw} [kg/m³] – density of non-wetting phase; ρ_w [kg/m³] – density of wetting phase; g [m/s²] – acceleration due to gravity; h [m] – column height of wetting phase; σ [kg/s²] – interfacial tension between the two phases; r [m] – radius of a pore at 10% saturation; θ [°] – wettability or contact angle between fluid and a solid (measured in the denser of the two fluid phases); all standard parameters taken from Yang & Aplin (1998 – and references therein) and Yaws (1999)

pore size distribution. Correction of the porosity-based model is not feasible since there is no physical correlation between total porosity and shape of the pore size distribution (Moore 2005). However, input parameters for the porosity-based model can be acquired at higher time- and cost-efficiency and thus have the potential to yield large data sets, and the scatter along the 1:1 correlation line in Figure 4–11 implies that the relative tendency of both methods is yet coherent to a reasonable extent.

Synopsis of Chapter 4 Grain and pore size properties of 92 mudrock core samples from various wells at various depths from the Nile Delta Plio-/Pleistocene section have been measured. Analysis of the property distributions allowed a rough allocation of recurring pore and grain size groups. However, considering the limitations that are outlined in Chapter 1.3 an integrated analysis of typical mudstone property groups as discussed by Moore (2005) is beyond the scope of this study.

Instead, propagation of the measured pore and grain size volumetrics along high-resolution core information such as photographs will yield both a detailed and coherent lithological description (and mudrock permeability tendencies) that can be set into context with hydrocarbon gas saturation and geochemistry. Such integrated relationships on the meso-scale will be discussed in Part IV of this thesis.

Chapter 5 Upscaling to the core and beyond

Genetic and/or textural rock units may be very useful to mediate between laboratory core sample and wireline log scale for calibration of petrophysical log signals such as porosity. In cored intervals, these lithological reference units can be manually derived from core images (CI).

However, definition of which does usually not obey any physical measurable rules but is subject to visual interpretation (*e.g.* Schieber 1999, Serra & Serra 2003 – and references therein). It is therefore desirable to validate the allocated lithological units in a quantitative and thus reproducible manner. Ideally, the resulting sedimentological profile has a tangible association to petrophysical profiles that are measured along the borehole wall during wireline logging. Establishment of this link would allow propagation of the lithological units along the entire log interval and attributed properties such as effective permeability could yield valuable input data for basin flow modelling (Drews 2011).

This chapter demonstrates that core image sections can be utilised for empirical propagation of rock sample information that was previously derived from laboratory analyses (Chapter 4). Figure 5–1 illustrates that core samples and wireline logs cannot be integrated without upscaling of sample properties to the closest associated log response. Here, it is suggested that the numeric information of core images enables a reliable upscaling of sample properties and thus calibration of petrophysical log models via semi-quantitative facies allocation.

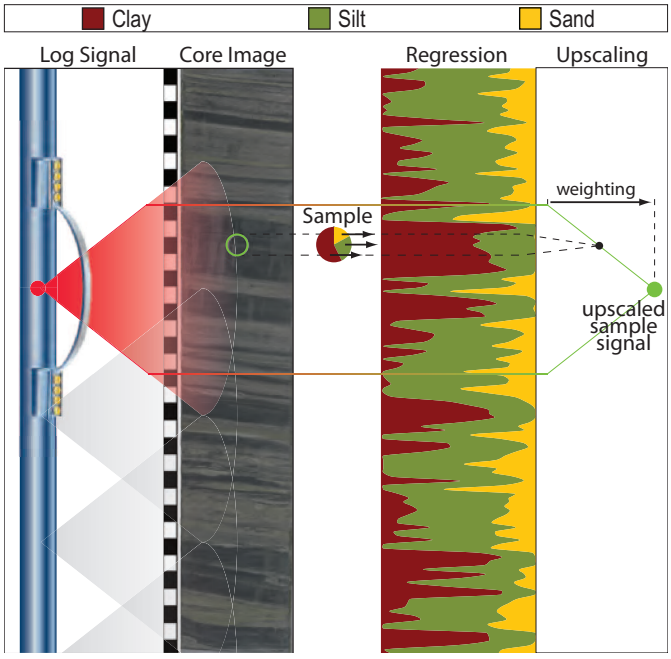

Figure 5–1 An intermediate scale is necessary to allow calibration of wireline log response with high-resolution and small-scale sample properties. Laboratory measurements of core samples have a resolution of 0.005-0.023 m, are usually scarce and discontinuously distributed along the borehole. In contrast, conventional wireline log signals provide continuous borehole information over several 100 m length, have a sampling step of usually ~0.15 m, and reflect the weighted average of petrophysical properties within the detectable formation volume.

Although laboratory experiments yield physically accurate rock properties on the smallest conventional scale – and given a borehole section of several kilometre length – related properties such as pore and grain-size distributions are usually scarce and can be considered unidimensional. Therefore, propagation of sufficiently accurate grain size and porosity models along core image

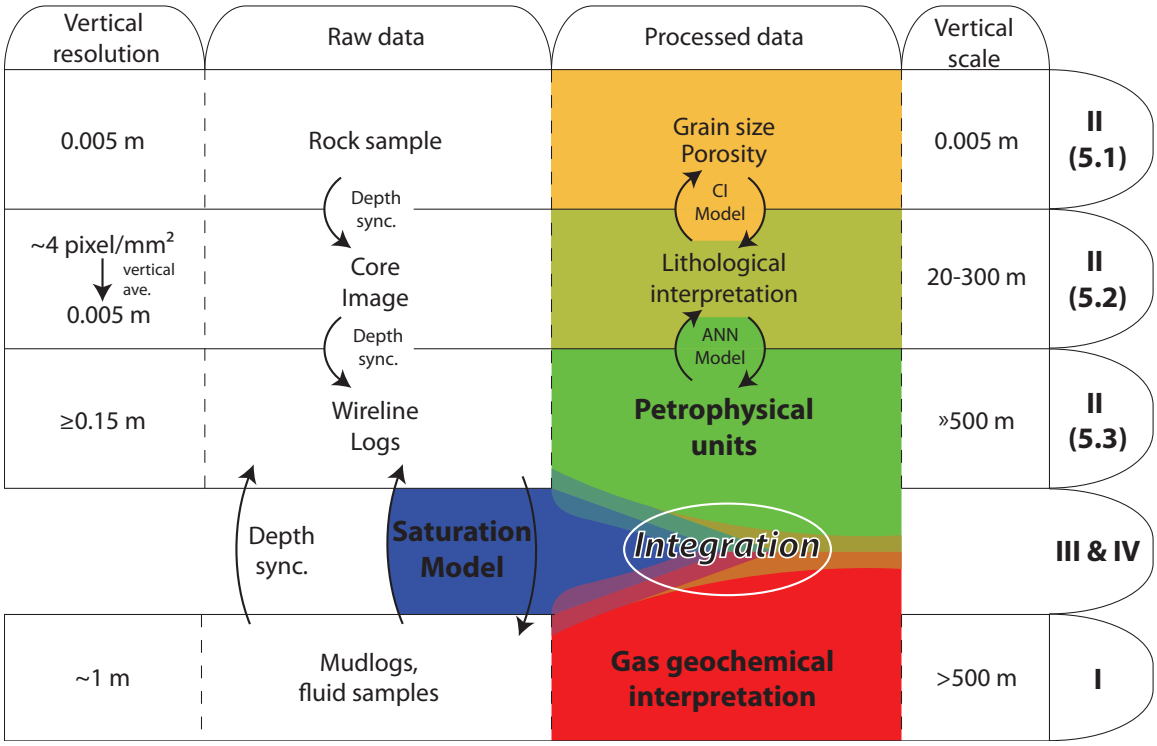

Figure 5–2 Workflow for lithofacies definition and their integration with gas volumetrics and geochemistry. Associated thesis parts (and chapters) are annotated in the right column. An empirical link between greyscale distribution parameters of the high-quality core images (CI) and specific grain-size fractions at the sample locations provided optical guidance for allocation of lithotypes (facies). Hereby calibrated lithotypes were reproduced by multi-dimensional mapping of their associated wireline log signals. The trained model has then been applied to the entire wireline logged section in order to obtain a complete lithological profile for each well.

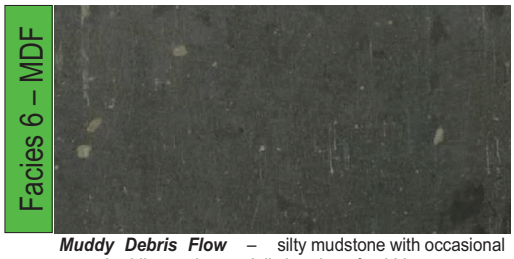
sections will help to define appropriate lithological units that are most likely reproducible from their associated wireline log signals (Fig. 5–2).

After a thorough synchronisation of core depth with logger's depth (Appendix A) the set of core facies can be used to supervise the training of conventional wireline log signals in an artificial neural network (ANN). Ideally, if the calibrated output wireline facies equal the input core facies the trained ANN will then provide an adequate lithological description of the non-cored borehole intervals, including most of the cap rock.

In summary, the most critical steps in the presented workflow for facies definition are as follows:



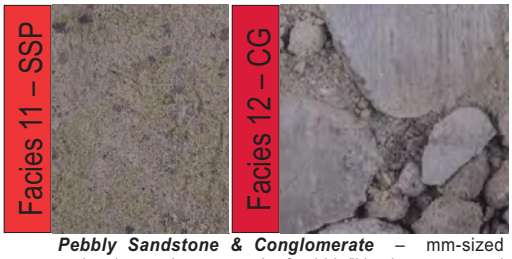
- Precise shifting of the core to the logger's depth (Appendix A)
- Definition and attribution of representative lithological core units (Chapter 5.1)
- Empirical validation of those units from a set of greyscale distribution parameters extracted from the associated core image intervals (Chapter 5.2)
- Satisfactory ANN calibration (Chapter 5.3)

A secondary aim of this study is to calibrate conventional wireline log models for porosity and clay content in siliciclastic sediments. The model will result in (a) high-resolution clay content logs for risk assessment of mud-rich seals via permeability calculations

(Yang & Aplin 1998 & 2004 2010) and (b) physically reliable porosity logs for hydrocarbon saturation models with focus on fine-grained sediments (Part III).

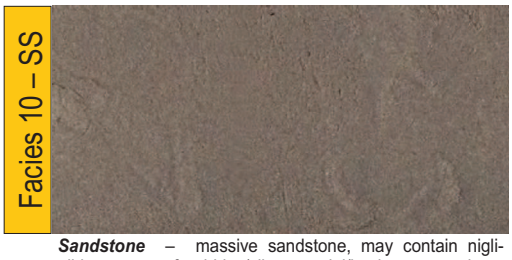
Initial core description Traditional facies interpretation relates the characteristic appearance of a given sediment package to its prevalent (*i.e.* primary and/or secondary) depositional environment (Füchtbauer 1988). The scale of these units may span from microfacies in thin sections to seismic bodies such as entire channels, mass transport formations or fault zones (tectonofacies). Inevitably, facies interpretation requires a sedimentologist to set his observations into an adequate palaeo-environmental context. Hereby, purely genetic descriptions may intermingle with textural attributes (Serra & Serra 2003), *e.g.* a pile of distal turbidites may be circumscribed by its fine-grained clastic laminae. However the scale, division of continuous lithological information into distinct units is generally subjective depending on the interpreter's perception and routine, especially if an interval has attributes of two or more divisions (*e.g.* "faint lamination but almost homogeneous").

Quantitative examination of lithological texture and composition have so far been focused on the microscopic scale (Schieber 1999 – and references therein). The facies scale of this study is in the decimetre to metre range as a consequence of the lowest resolution data that is intended to be set in lithological context, namely gas samples (~1m) and wireline log information (≥0.15m). In order to set a starting situation the available core photographs and microresistivity borehole images were interpreted in terms of the 13 most characteristic recurring rock features, comprising 6 mudrock facies, 6 sandy facies and a carbonate facies (Fig. 5–3; see Appendix B for a full review). This preliminary subdivision forms the basis of subsequent validation and re-evaluation with empirical grain size distributions and associated log signals as documented in the following chapters.



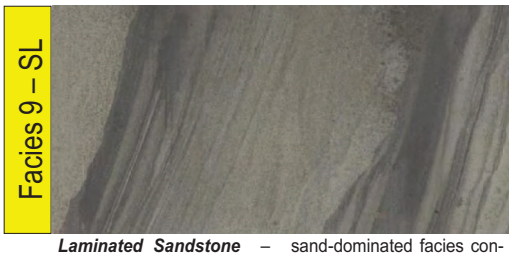
Muddy Debris Flow – silty mudstone with occasional cross-bedding and potentially bearing of pebbles

Argillaceous Limestone – any rock section suspected of containing significant ("visible") amount of argillaceous carbonate, by experience often related to fossil shells



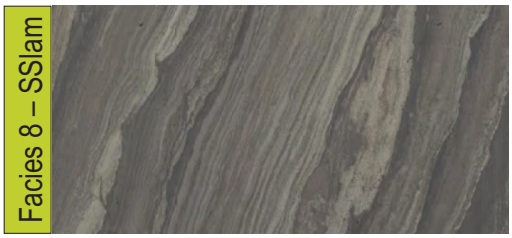
Chaotic Mudstone – clay-bearing facies with high proportion of secondary sandy features (such as SS-intrusions, mingling/slumps, brittle zone containing coarse fault gauge)

Pebbly Sandstone & Conglomerate – mm-sized grains in sandstone matrix &pebble/lithoclast supported matrix (similar to some broken core sections)



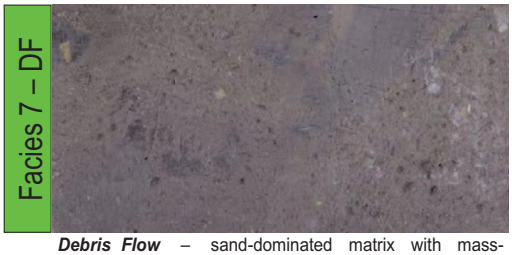
Slumped Mudstone – clearly mudrock-dominated facies with slump-features and/or brittle deformation

Sandstone – massive sandstone, may contain nigligible amount of pebbles/silty material/laminae, sometimes quite "dirty" but homogeneous



Silty Mudstone – silty dark mudstone, "reworking" optional

Laminated Sandstone – sand-dominated facies containing significant amount of silty laminae/sections



Laminated Mudstone – mudstone dominated facies with a significant proportion of sandy/silty layers, maybe slightly slumped if continuity of laminae is preserved

Sand/Silt Laminae – sand/silt/mudstone laminae

Massive Mudstone – massive "featureless" mudstone, may contain vague laminae/slumps/mudflakes if effect on bulk poroperm properties is considered insignificant

Debris Flow – sand-dominated matrix with mass-transport features (*e.g.* directed clasts/flakes) and/or more subtle features such as remnants of reworked SS-laminae

Figure 5–3 Lithofacies definition scheme and allocated colour code. A complete template that describes the entire variety of each facies can be reviewed in Appendix B.

5.1 Propagation of matrix and pore properties

The initial motivation to relate CI properties and petrophysical measurements was fuelled by ambiguities in siltstone facies allocation from visual core image inspection. Identification of silty mudrock intervals is essential for seal risk assessment because of a substantial pore size difference between matrix-supported to framework-supported textures (Moore 2005). However, a few dozen grain size analyses are not sufficient to assess hundreds of metres heterogeneous cap rock lithology. This chapter deals with the possibilities to overcome this scale gap by deriving continuous grain and pore size information from core images, hereafter referred to as core image-to-grain size (CIGS) model.

There are two fundamental ways to obtain grain size estimates from photographs of (unconsolidated) clastic sediments: a geometrical and a statistical approach (Buscombe *et al.* 2010 – and references therein). The former relies on 'advanced sequences of image processing to isolate and measure each individual grain' (Buscombe *et al.* 2010), usually resulting in computed grain size distributions where the smallest detectable grains have a diameter of at least one image pixel. This method is unsuited for studies of fine-grained sediments such as mudrocks. Instead, a statistical approach has been chosen assuming that an empirical correlation exists between grain (and pore) size fraction and parameters that describe the greyscale distribution of core images. Buscombe *et al.* (2010) point out that such statistical methods so far did not have the power to generate the entire grain size distribution but rather specific features of interest such as the mean grain diameter.

On a macroscopic scale, the human eye is only capable of vague end-member discrimination between clay-rich and sand-rich rock specimens. Sandstones are usually bright and contain individual grains that can be readily identified by brief visual inspection. In contrast, massive mudstones deposited under anaerobic conditions such as in the Nile Delta are dark due to a mixture of opaque minerals and organic matter and have a rather smooth and often homogeneous, sometimes shiny profile. These properties can be described by basic greyscale distribution parameters of core image pixel rows, with greyscale units (GSU) commonly between 20 (dark) and 200 (bright). The distribution parameters used are average (CI_{ave}), median (CI_{med}), and modal (CI_{mod}) greyscale and variance (CI_{var}). The former three describe the representative luminance and its bulk variance can be considered as a measure of "coarseness" of the photographed rock; in principle very similar to the criteria a human eye would pick up.

The results of an initial test of whether these observations can be reproduced by the derived CI parameters were positive (Fig. 5–4). If the transition between clay-to-sand extremes can be approximated with a function that fits the measured grain size data, for

instance, siltstone facies might be determined from core images to an extent and coherency that lies beyond the interpreter's perception. Therefore it has been decided to start off with a CI multi-regression towards average clay (<2 µm) and sand fraction (>63 µm).

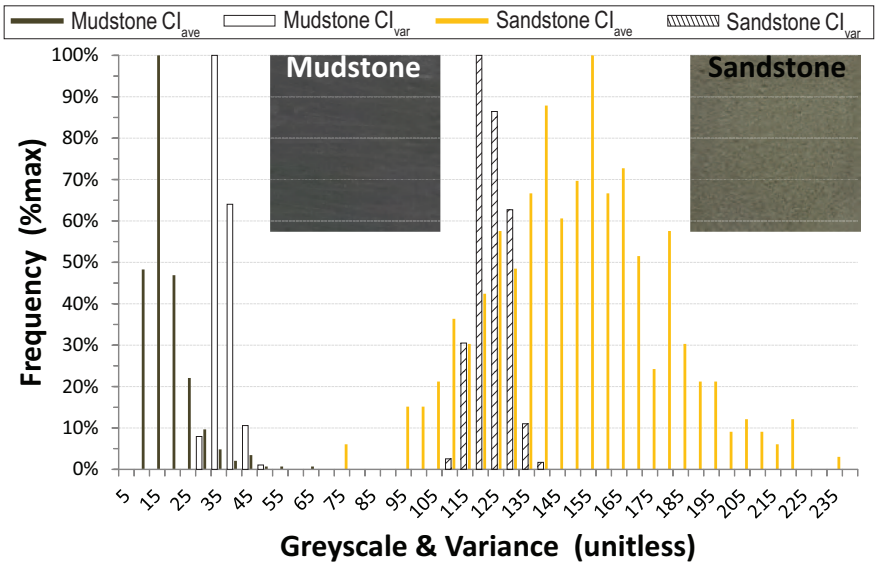


Figure 5–4 CI parameter distributions of a "typical" mudstone (B19: 1656.24-1656.34m) and sandstone (B24: 1999.32-1999.42m) profile. Sandstones are brighter and display greater variance compared to mudstones.

Input data Prior to investigation of the interrelationships between petrophysical information and optical core properties the source of the latter – namely the core photographs – requires a quality control assessment to validate the coherency of input data.

Each image comprises 70 cm of even rock surface from the central plane of a split core followed by a 30 cm gap of plain white where samples were removed prior to photography. Scale bar and colour patches are enclosed for reference. Further, the camera angle was vertical during exposure and illumination is found to be consistently saturated and balanced (Fig. 5–5). These observations affirm that the CIs have been taken under consistent laboratory conditions.

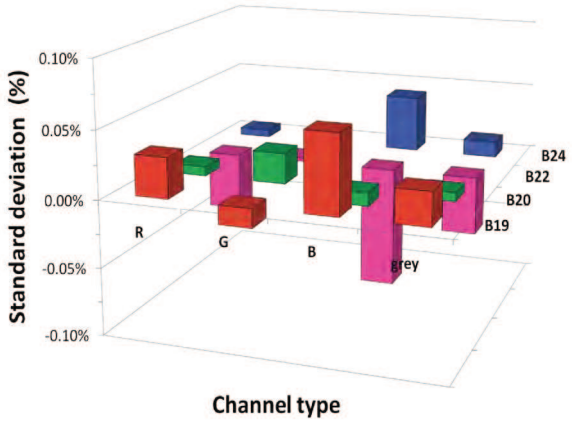

Figure 5–5 The core photograph settings of all 4 calibration wells are similar with a deviation of <1%. See Fig. 5–6 for example colour patch. Data by courtesy of M. Drews.

The photographs have originally been stored in the RGB colour model, *i.e.* each pixel is equipped with a combination of numeric red, green, and blue shades. Overlay of all three channels in the numerical 8-bit byte system can result in 255^3 individual colour combinations that are commonly described by RGB triplets, *e.g.* (255,0,0) for pure red or (64,224,208) for turquoise etc. In order to narrow this vast colour range for feasible statistical analysis the RGB channels were averaged to a single greyscale

channel with units between 0 (black) and 255 (white).

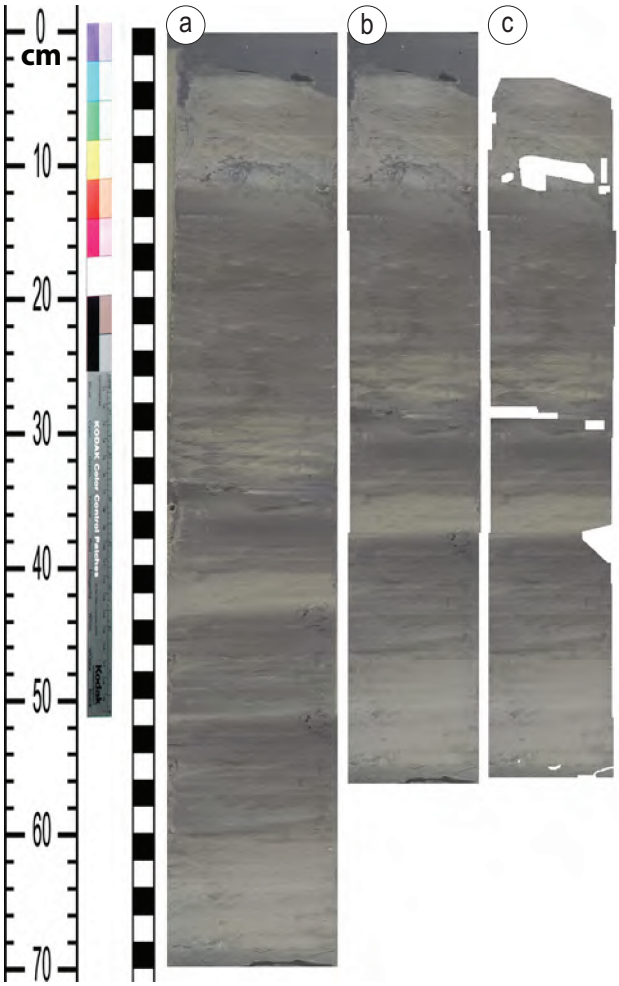

Figure 5–6 (a) Raw, (b) cropped and corrected, and (c) cleaned core image (example from Well B20: 1734-1734.7m). Removed features include cracks/fissures, annotations, preservation resin, moisture/dessication marks, empty and filled plug sampling holes, brush streaks, fingerprints and all kinds of dirt including human hairs and loose grains.

However, some core sections have been affected by superficial contaminants or local loss of physical integrity. These artefacts of core recovery and preparation were carefully post-processed with white pixels (equiv. 255 GSU) since very light rocks such as chalk or other carbonates are absent from the investigated stratigraphy. White can thus be numerically removed during further image processing (Fig. 5–6). Another severe image bias depicted in Figure 5–6 is the sporadically occurring duplication of image sequences. From experience these artefacts originate from erroneous stitching of overlapping (digital) images and pose a substantial threat to apparent core continuity. Fortunately, careful investigation revealed only a dozen of these phenomena (mostly from Well B20) where remediation has been feasible.

As mentioned above, the white end-member represents unpreserved or biased rock information and is therefore neglected, *i.e.* pixel ranks that are separated by deleted (white) sections are closed in order to obtain a continuous (shorter) row. This procedure allowed to determine basic statistical parameters such as the mean, median, mode, and variance to describe the greyscale distribution of any row longer than 30 pixels. An uncertainty test for all 14 sample locations

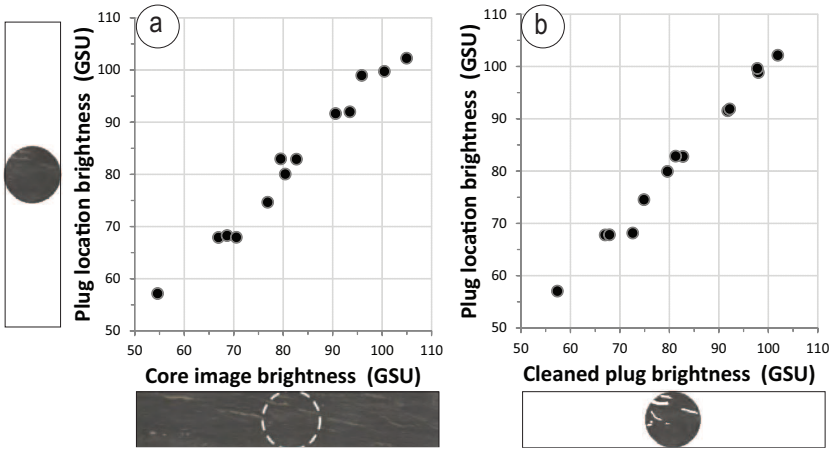

Figure 5–7 Plug image properties are (a) insusceptible to sub-mm-scale CI stains and (b) reflect the image properties of the full core width at the associated location (Well B19 examples).

of well B19 (Fig. 5–7) suggests that these very high resolution logs provide relatively rigid input data for the search of empirical correlations to the laboratory rock measurements.

Barring input quality, the outcome of the intended statistical analyses may be diagnostically conclusive only under consideration of input scale consistency. Therefore, the bulk of the core images from the wells of interest have been down-sampled to a common resolution of 3467 pixels/m (12 pixels/mm²). Finally, the images could be examined for statistical information that is purely rock-related.

The CIGS model The biggest obstacle was to determine the influence of precision in the recorded core sample depth, since allowing the sample location to vary can easily lead to subjective shifts that foster a high correlation coefficient. Although the general uncertainty with this issue is outlined in Chapter 1.3 it needs to be restated that neither the stratigraphic inclination relative to the borehole orientation, nor the exact location and angle of the drilled plug relative to the core (Fig. 5–8), and not even the exact location(s) of the measurement sub-samples relative to the plug is recorded.

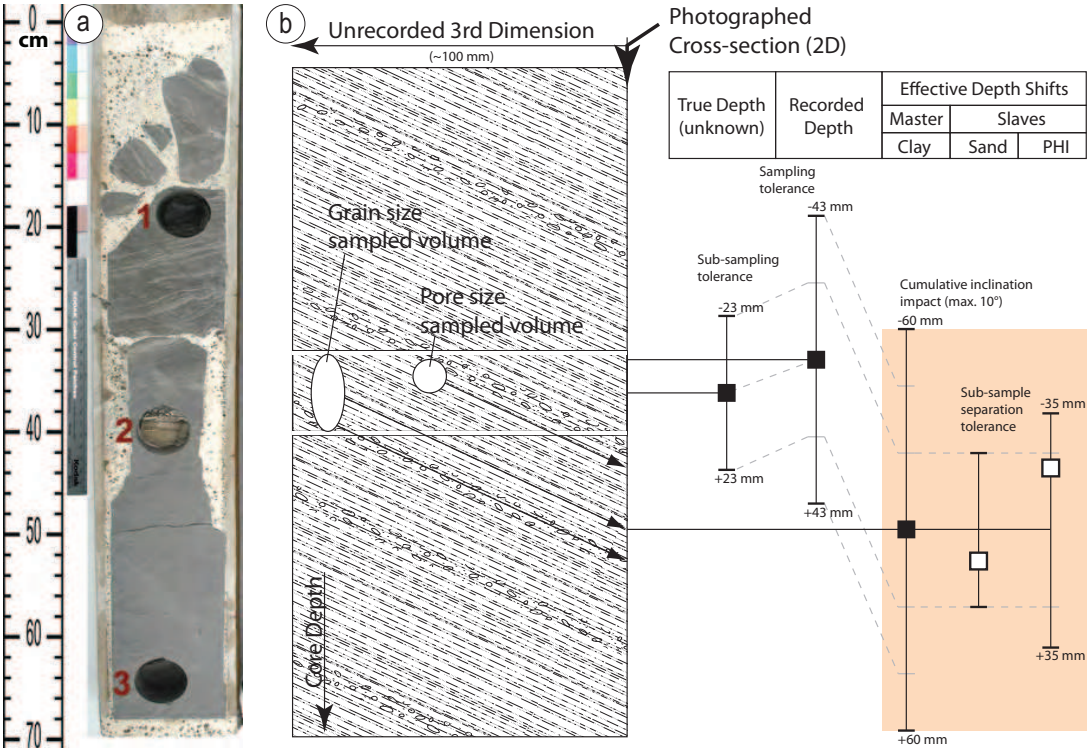

Figure 5–8 Inaccuracies in plug sampling depth by up to 2 cm (example from well B9, core depth 1922-1922.7 m; alleged sample depth: 1 – 1922.18 m; 2 – 1922.38 m, 3 – 1922.63 m) contribute to the overall uncertainty of approx. +/- 6cm.

Further, one needs to be aware that sub-samples for different laboratory analyses have been taken from different parts of the core plug. In other words, porosity and grain-sizes cannot be measured from exactly the same piece of rock. In case of homogeneous plugs this issue is possibly negligible, but as soon as there is micro-lamination involved the two sub-samples might have substantially differing properties. Hence it has been clear from

the beginning that working with static sample depths would not lead to a satisfying result. To minimise the risk of subjective sample shifting the well with the apparently most homogeneous CI sections in the vicinity of alleged sample locations has been chosen: B19.

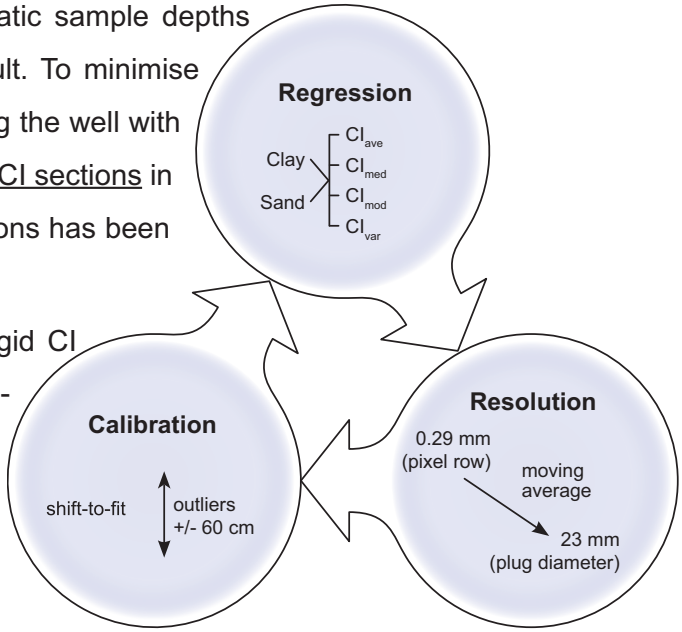

Figure 5–9 Iterative workflow for sample-to-CI grain size integration as a consequence of effective sample depth and resolution uncertainties.

Establishment of a sufficiently rigid CI model required tedious trial-and-error procedures (Fig. 5–9). The best fit between sampled grain size fractions and core image parameters of 16 quality mudrock samples from Well B19 led to the following empirical relations (Equs. 5a-b).

$$\text{Clay [\%]} = 140 + 6.83 \cdot CI_{ave} - 7.75 \cdot CI_{med} - 0.242 \cdot CI_{var} \quad | \; R^2=0.95 \qquad \textbf{(5a)}$$

$$\text{Sand [\%]} = -8 - 0.796 \cdot \text{EXP}(CI_{ave}/20) + 0.918 \cdot \text{EXP}(CI_{med}/20) + 0.0675 \cdot CI_{var} \quad | \; R^2=0.99 \qquad \textbf{(5b)}$$

Strictly, these formulae are applicable to the grain size range of the reference laboratory measurements. Modelled values outside the range from 0% to 100% required normalisation (Equs. 5c-d; see also Fig. 5–10).

$$\text{Clay}_{norm} \text{ [\%]} = \text{Clay} / \text{SUM}(\text{Clay,Silt,Sand}) \cdot 100 \qquad \textbf{(5c)}$$

$$\text{Sand}_{norm} \text{ [\%]} = \text{Sand} / \text{SUM}(\text{Clay,Silt,Sand}) \cdot 100 \qquad \textbf{(5d)}$$

The fundamental sand equation (5b) includes two exponential expressions that provide the non-linear boundaries in the sand-*vs*.-clay plot (Fig. 5–10c). This feature is important since it leaves space for the intermediate grain-size: the silt content.

When estimating porosity and permeability from grain-size properties of fine-grained

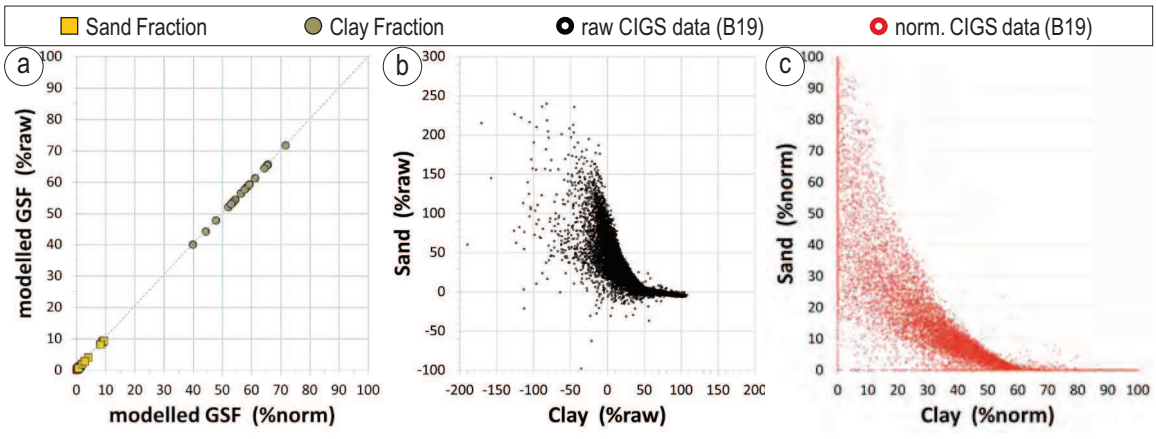

Figure 5–10 (a) Final calibration and (b) sand vs. clay cross-plot of the raw model output for well B19 before (c) normalisation. The normalised model results in clay and sand fractions which sum up to a value of less than 1, leaving the remaining space for silt content.

sediments it may be useful to generate additional information about the distribution of cohesive silt (ChS, 2-10µm) and coarse silt (CrS, 10-63µm). Using the available database of 343 grain-size analyses from the Nile Delta area (see Appendix C) it is possible to narrow the cohesive-to-coarse silt range as a function of clay and sand content (Equ. 5e).

$$CrS_{static}\,[\%] = 123 - 1.26 \cdot Sand + 1.2 \cdot Clay + 4.25 \cdot SQRT(Sand) - 23 \cdot SQRT(Clay) \quad | \quad R^2 = 0.83 \qquad \textbf{(5e)}$$

However, the absence of a strict cause-and-effect relationship in Equation 5e leads to an insufficient coverage of the measured silt ratio range in Figures 5–11a and 5–11b. It was therefore necessary to implement a random number function that covers the measured data scatter (Equs. 5f-g).

$$CrS\,[\%] = \tfrac{1}{2} \cdot CrS_{static} + \tfrac{1}{2} \cdot RANDBETWEEN(CrS_{static} \pm 20\%) \quad | \quad CrS\,[\%] \in \{0, CrS_{static} + 20\%\} \qquad \textbf{(5f)}$$

$$ChS\,[\%] = 100 - Sand - CrS - Clay \qquad \textbf{(5g)}$$

This is the best solution since it is not being dealt with a representative data set, *i.e.* utilisation of weighted probabilities in order to further confine this range is not justified. As expected, the modelled cohesive-to-coarse silt ratios fall within realistic ranges (Fig. 5–11c).

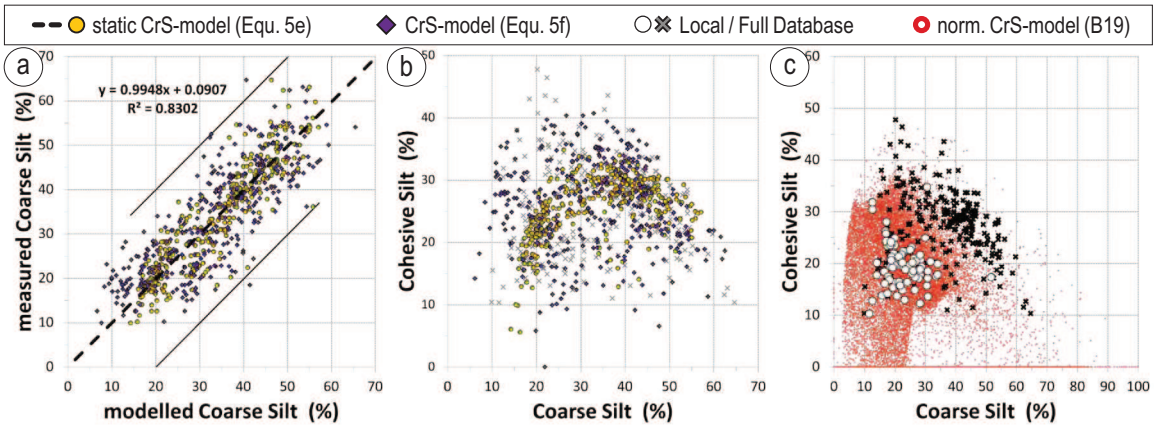

Figure 5–11 (a) Cross-plot between modelled and measured coarse silt content and (b) range of cohesive-to-coarse silt relation both with initial regression and random number weighting of 50%. (c) The output of the CrS-model for well B19 falls within the expected range of local grain size measurements from wells B19/20/22/24 and the rather silty samples from other Nile Delta wells.

Calibration & Harmonisation The precept of coherency calls for an expansion of the empirical relations found for well B19 towards a generic model that can be applied to any core interval recovered from siliciclastic sediments. Given the poorly constrained sample-to-depth uncertainties (Figs. 1–14, 5–8, and 5–9) it is not advisable to establish individual models for each alternative Nile Delta well. Although initial tests suggested that the regression technique is universally applicable, it led to strongly well-specific empirical equations (not shown). This observation clearly clashes with the consistent CI quality described earlier.

As it turned out, further investigations revealed a strongly linear shift between the CI

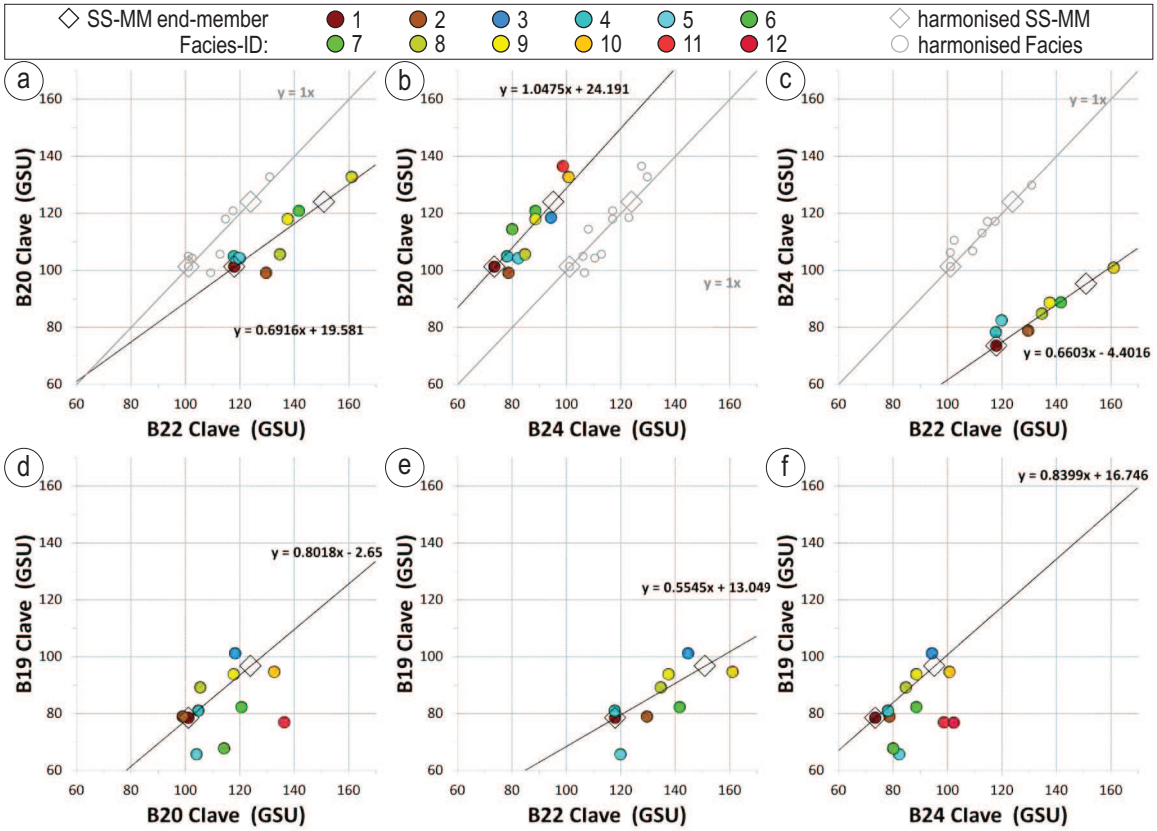

Figure 5–12 Cross-plots between the average CI brightness of allocated facies intervals from the wells under consideration. (a-c) The good correlation seems to be a function of core moisture given that the photo quality is comparably consistent between the wells. (d-f) Some of the sand-rich facies in the reference well (B19, see y-axes) substantially deviate from the findings of the remaining wells. See Figure 5–3 for facies description and colour coding.

brightness of the four wells under consideration (Fig. 5–12). The simplicity of this core interrelation suggests that it reflects bulk moisture variations of the photographed rock surface. Hence, the systematic offset between the wells is interpreted as an expression of wellsite specific core management in the period between its recovery and photography.

It is further proposed that the scatter in Figures 5–12a-c originates from fundamental lithological differences between the well locations and possibly some inaccurate facies allocations. Therefore it seemed advisable to use the average brightness of the massive mudstone facies (MM) and sandstone facies (SS) for end-member regression. Since some sandy sections from well B19 appear suspiciously dark (Figs. 5–12d-f) this approach fosters the opportunity to check the brightness distribution of all alleged sandstone intervals (incl. laminae) for quality control (Fig. 5–13).

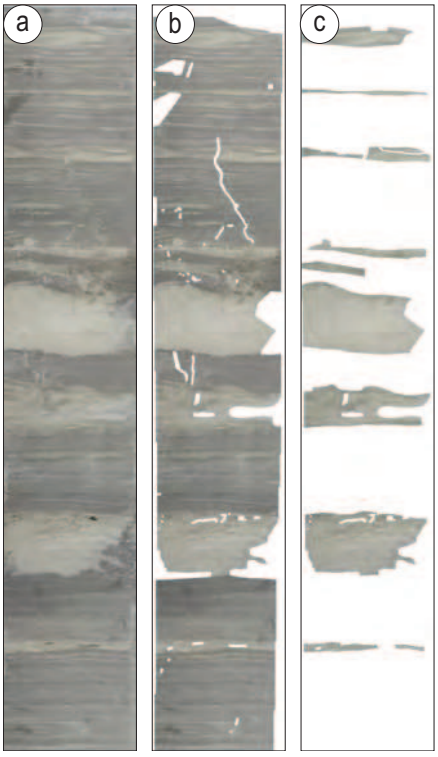

Figure 5–13 (a) Original, (b) cleaned/cropped, and (c) sand-filtered core image (example facies 8 from well B22, core depth 1726-1726.7 m)

As suspected the strong bimodal distribution of B19 sand brightness affirms the existence of continuous intervals that have a brightness anomaly, hereafter referred to as dark sandstone anomaly (Fig. 5–14). It remains unresolved whether this bias is related to *in situ* conditions (*e.g.* sedimentary organic matter, residual oil stains/ palaeo-biodegradation) or drilling and recovery processes (drill mud contamination). Nevertheless, the proposed harmonisation of the empirical formulae required a reasonable correction for the dark SS anomaly.

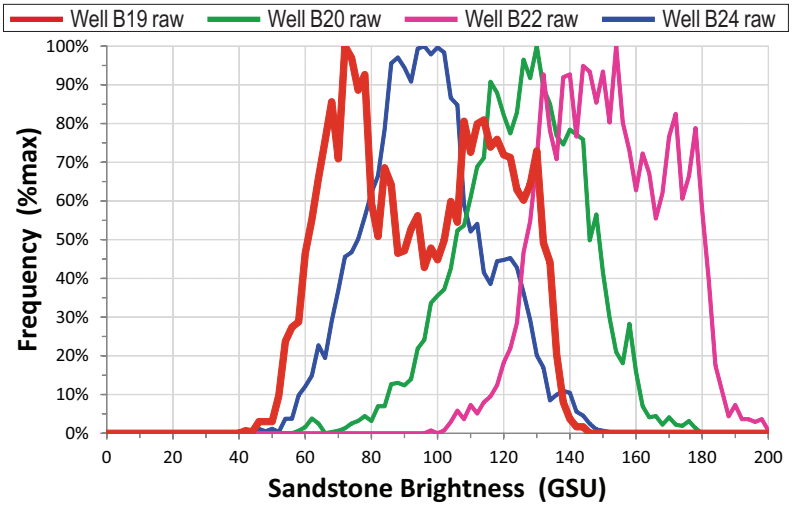

Figure 5–14 The lower mode in well B19's distinctive distribution of cropped sand brightness represents a dark sandstone anomaly. Offsets relative to the remaining wells are subject to differential core moisture, as explained in the text.

Greyscale correction of the dark SS anomaly in parts of well B19 requires discrimination from the normal or clean intervals. A subjective allocation of "dark" and "clean" has been rejected for reasons of poor reconstruction. In addition, naturally dark laminae could easily be overridden during manual picking. An initial concept to utilise COGR signals failed for reasons of scale, resolution, and depth mismatches (see Appendix A). Alternatively, the definition of a lower limit cut-off for natural SS brightness in B19 has been defined by temporary bulk harmonisation of the four SS distributions (Fig. 5–15). Trial-and-error tests with running average brightness on all four wells have shown that for the pristine wells only 0.8-3.1% of their total sandstone sections fall below the defined cut-off when applied to the 10 cm vertical mean, opposed to 27.3% for the biased well B19. At the same time, dark pixel rows from B19 that were not marked from this screening procedure fall within the range of the SS reference wells, and manual inspection of the

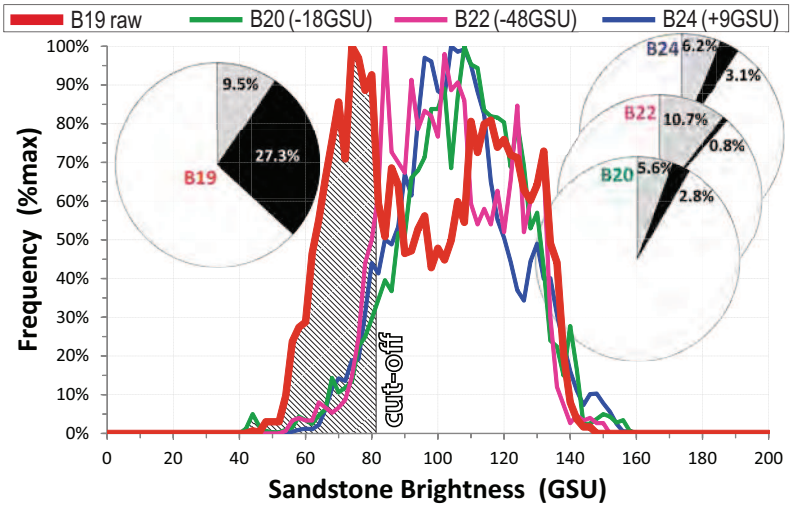

Figure 5–15 Normalisation of the mean brightness in sandy sections reveals the dark sandstone peak in B19. In the critical zone (hashed area) it is the proportion of brightness averaged over a vertical 10 cm (black pie chart area) that picks up the biased sections. This procedure enables filtering for naturally occurring dark laminae (grey pie chart area) prior to correction of B19's sandstone distribution.

detected dark sand sections affirmed that the method successfully skipped unsuspicious sand features such as naturally dark laminae.

Corrections can be applied without affecting the mean of the believable sand distribution by simple superimposition with the biased distribution (Fig. 5–16a). This procedure is acceptable given that no grain size calibration data from sandstones is available, that this study focuses on fine-grained sediments, and that the CI harmonisation aims for the MM and SS mean. Also, pebbly and conglomerate sections have in principle been neglected in this study (Fig. 5–16b).

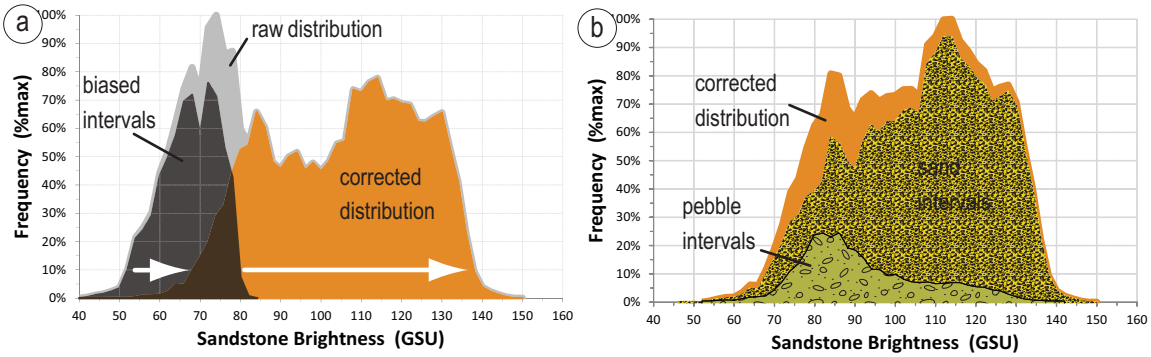

Figure 5–16 (a) Superimposition of the isolated dark SS anomaly onto the believable ("healthy") distribution is considered valid since it does not modify its mean (see text). (b) Splitting of the fixed SS distribution into sandy sections (facies 10 and below) and pebbly/conglomerate sections (facies 11/12) indicates that the latter show a strong skew towards the darker end which will be due to dark macro-grains. Since those grains will also lead to a lower CI variance the associated sections are not compatible with the concept of the applied grain size model and have hence been neglected.

Still, although this procedure does reproduce the original distribution of sandy sections to reasonable extent the exact motion path from "clean" to "dark" of each individual pixel row cannot possibly be inverted simply because that information is lost. Hence, the CI parameters of the three remaining wells were harmonised to the B20 slope (Figs. 5–12a-b) before referencing to B19 (Fig. 5–17).

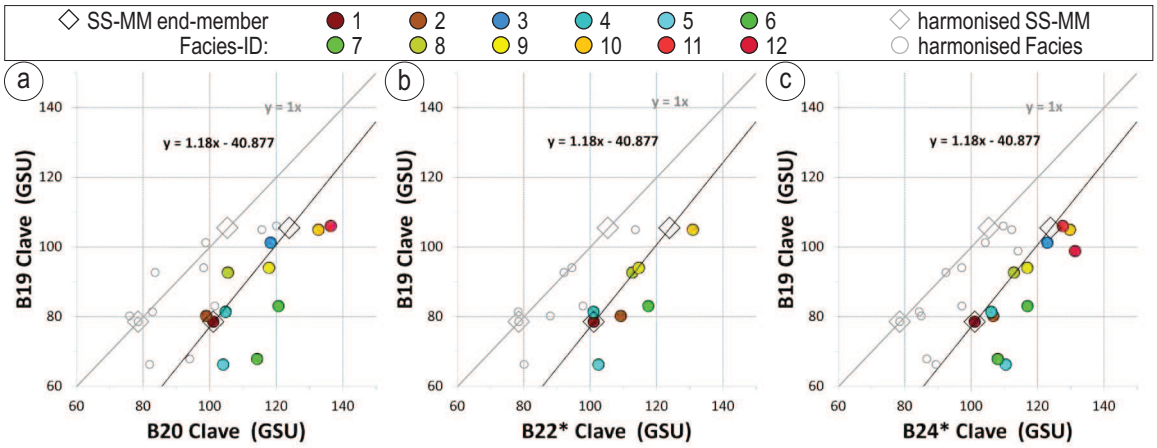

Figure 5–17 The cross-plot between average facies greyscales of the B20-harmonised wells (asterisked; see text) and SS-corrected B19 yields an improved trend that can be used for CI harmonisation between all of the four priority wells.

The resulting differences in linearity between the average clay and sand end-members

of the non-harmonised CIs directly represent differing core moisture conditions (Fig. 5–18a). The mean sandstone brightness for each of the three linearly adjusted CI sets resembles the manual bulk shift that was previously applied for quality control (Fig. 5–15), *i.e.* the initial cut-off for the dark SS anomaly in B19 is sufficiently well constrained.

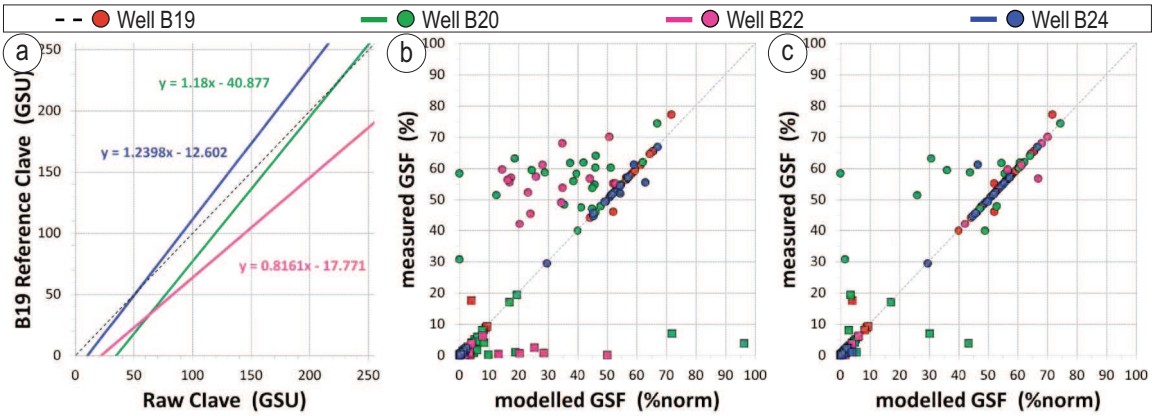

Figure 5–18 (a) Linear relations for CI harmonisation show that B22 had the dryest core whereas the freshest was photographed from B24. When recalculating the CI parameters with these formulae it is important to remember that the variance equals the square of the standard deviation, *i.e.* linear variance modification proceeds using the square of the function's slope. The modelled values of (b) the B19 calibration are substantially enhanced (c) upon application of the well-specific harmonisation functions. See text for discussion.

Further, application of the CIGS model from B19 to the harmonised wells yields a very satisfactory result (Figs. 5–18b,c). However, some measurements from B20 could not be modelled correctly. Underestimated clay content and overestimated sand content could be an indication that one ore more of the B20 cores has been exposed to the atmosphere for a longer time period before photography than other, leading to a stronger brightening from dessication and thus a bias in the model. However, the overwhelming majority of data points that fit the equations at the proposed sample scale (5 mm) allows a careful application to the discrimination of mudstones from siltstones at the facies scale (≥ 5cm). The total range of the calibrated and harmonised 3-fold grain size distributions along with probability densities of coarse and cohesive silt fractions is shown in Figure 5–19.

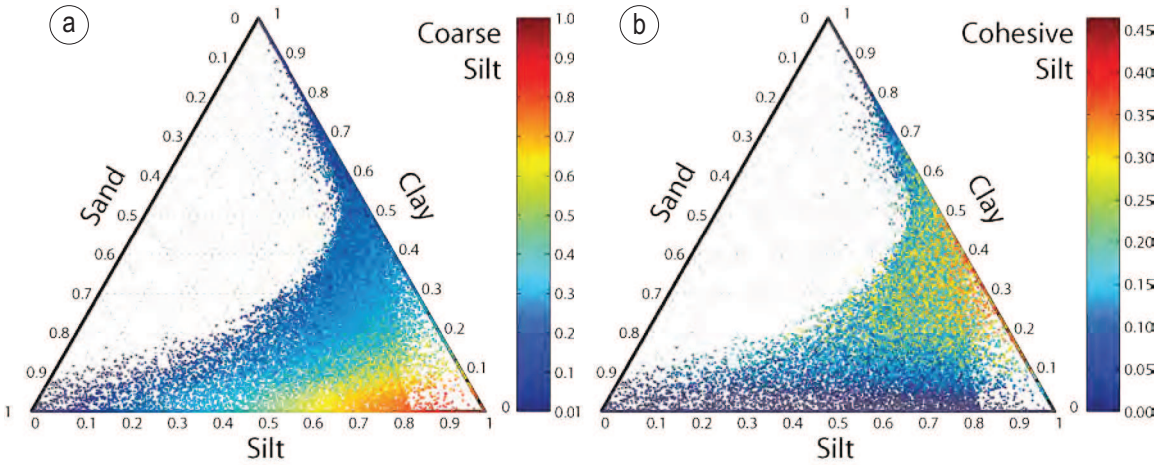

Figure 5–19 Generated distribution in volume fraction for (a) coarse silt and (b) cohesive silt in the ternary grain size diagram.

Porosity and permeability propagation While the grain size distribution describes the matrix or structural framework of a sediment it does not, however, give quantitative information about the associated pore volume. In fact, diagenetic processes such as compaction and cementation need to be accounted for when considering the pore space estimation over a great depth range.

Fortunately, the Pliocene section of the Nile Delta stratigraphy does not contain any major carbonate deposits that could have suffered severe calcite cementation via dissolution/precipitation processes. Likewise, formation temperatures barely exceed 80°C which technically precludes quartz cementation from mineral diagenesis such as smectite-to-illite transition (Bjørlykke 1998). Accordingly, mechanical compaction is the sole additional factor that needs to be considered when deriving a porosity estimation from CI parameters. The best model (Fig. 5–20) was found when incorporating lithostatic stress σ (Equ. 5h, *cf.* BP Egypt) and the compaction coefficient β (from Yang & Aplin 2004).

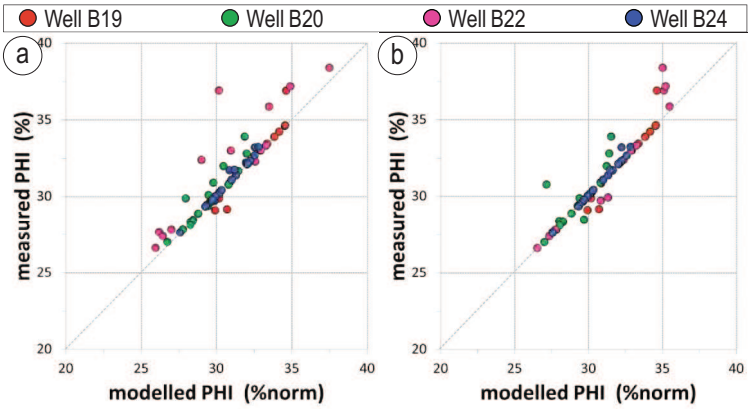

Figure 5–20 Porosity model for (a) the raw CI parameters and (b) the harmonised parameters. No normalisation was required since the model appears comparably insensitive to manipulation of the original CI parameters. This observation may be explained by the small overall porosity range and the sample depth fitting.

$$\sigma\,[\mathrm{MPa}] = 7.26177\cdot10^{-7}\cdot\mathrm{MDSB}^2 + 1.86055\cdot10^{-2}\cdot\mathrm{MDSB} \quad | \; R^2=1.0 \qquad \textit{(5h)}$$

$$\varphi\,[\%] = -20.8 + 0.241\cdot CI_{ave} + 0.0565\cdot CI_{var} - 0.185\cdot CI_{mod} - 0.979\cdot \mathrm{EXP}(CI_{ave}/20) + 1.12\cdot \mathrm{EXP}(CI_{med}/20)$$
$$- 0.431\cdot\sigma + 93.3\cdot\beta - 0.858\cdot\mathrm{Sand} + 0.532\cdot\mathrm{Silt} \quad | \; R^2=0.90 \qquad \textit{(5i)}$$

The average porosity *versus* burial depth curve for the cored Pliocene mudstones of the western Nile Delta fan is shown in Figure 5–21. Further, modelled porosity and grain size logs enable the high-resolution study on mudstone permeabilities according to the empirical formulae of Yang & Aplin (1998 2010), as outlined in Chapter 4.2. The porosity curve can be used to calculate a global permeability-depth path (Fig. 5–22a) from the peak frequencies in hypothetical permeability distributions of the Pliocene mudstones (facies 1-4) at any given burial depth (Figs. 5–22b-c). Such synthetic diagrams could provide probabilistic flow rate boundaries for mudstone grid blocks in regional basin models. In this study, however, the derived porosity (and permeability) data will be used to calibrate wireline porosity logs as important input parameter for the hydrocarbon saturation model in Part III.

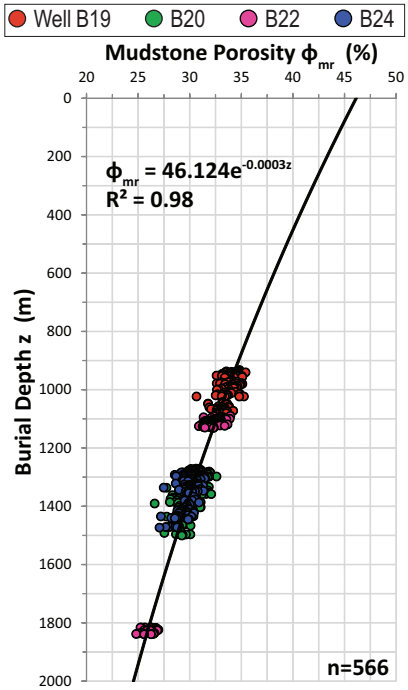

Figure 5–21 The global (10m) average of mudstone porosity (φ_{mr} of facies 1-4) yields an exponential decline with increasing burial depth.

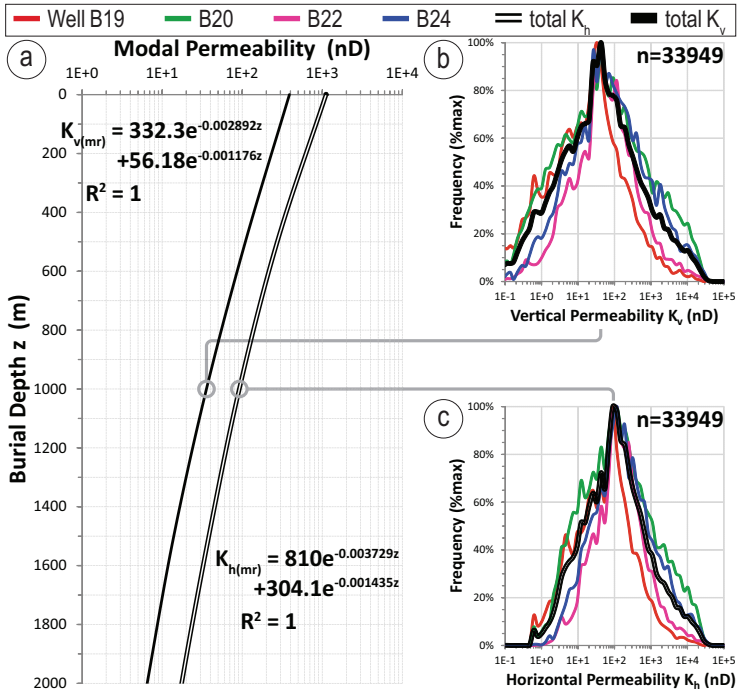

Figure 5–22 (a) Modal permeability-vs.-burial depth path for an undistinguished Pliocene mudstone in the western Nile Delta fan. Distribution plots refer to 5mm-scale (b) vertical and (c) horizontal mudrock (mr) permeabilities (K_v and K_h) at a mechanical compaction equivalent to 1000 m.

Validation An automated scan was performed to establish the best-fit between measured grain/pore size data and core parameters (in Figs. 5–18c and 5–20b) within the uncertainty range of the sample depth (Fig. 5–8). Analysis of the resulting sample shifts along the core yields valuable information about the validity of the proposed depth uncertainty.

The sample depth shifts resulting from the master auto-scan (aided by a simple algorithm; see Fig. 5–8b for disambiguation) that matches modelled with measured clay content are predominantly situated well within the vertical shift window of ± 60cm (Fig. 5–23a). Given the variety of factors that caused the discrepancy between recorded and

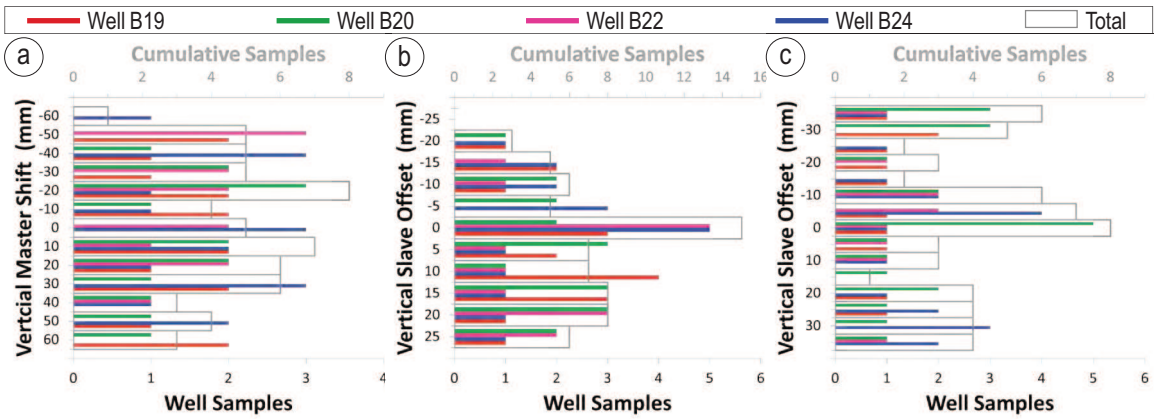

Figure 5–23 Distribution of sample depth shift in order to meet the measured rock properties. (a) Master shift for the clay fraction model, and slave shifts relative to the master shift position for (b) sand model and (c) porosity model.

true sample depth the master shift distribution is not expected to reveal any more explicit cumulation near the central position.

In contrast, the slave shifts (Figs. 5–23b-c) especially of the sand regression but also to some lesser extent of the porosity model are by definition spatially related to the clay master position (see Fig. 5–8b). As this dependency has initially been only of theoretical nature upon integration of clay, sand, and porosity model the presence of a unimodal distribution for sand shifts (Fig. 5–23b) now supports the validity of the model set up and affirms that a sand signal can be picked up from clay-dominated core intervals. Further, the bi-to-trimodal distribution for porosity shifts (Fig. 5–23c) affirms that a significant number of porosimetry samples have a slightly but distinctively different effective depth than the grain size samples, depending on where exactly the sub-samples have been taken within the three dimensions of the core (see Fig. 5–8b).

Comparison of modelled porosity *vs*. clay with wireline log PHIND *vs*. VSH interrelations (Fig. 5–24) largely validate the applied PHI-model given that no wireline log harmonisa-

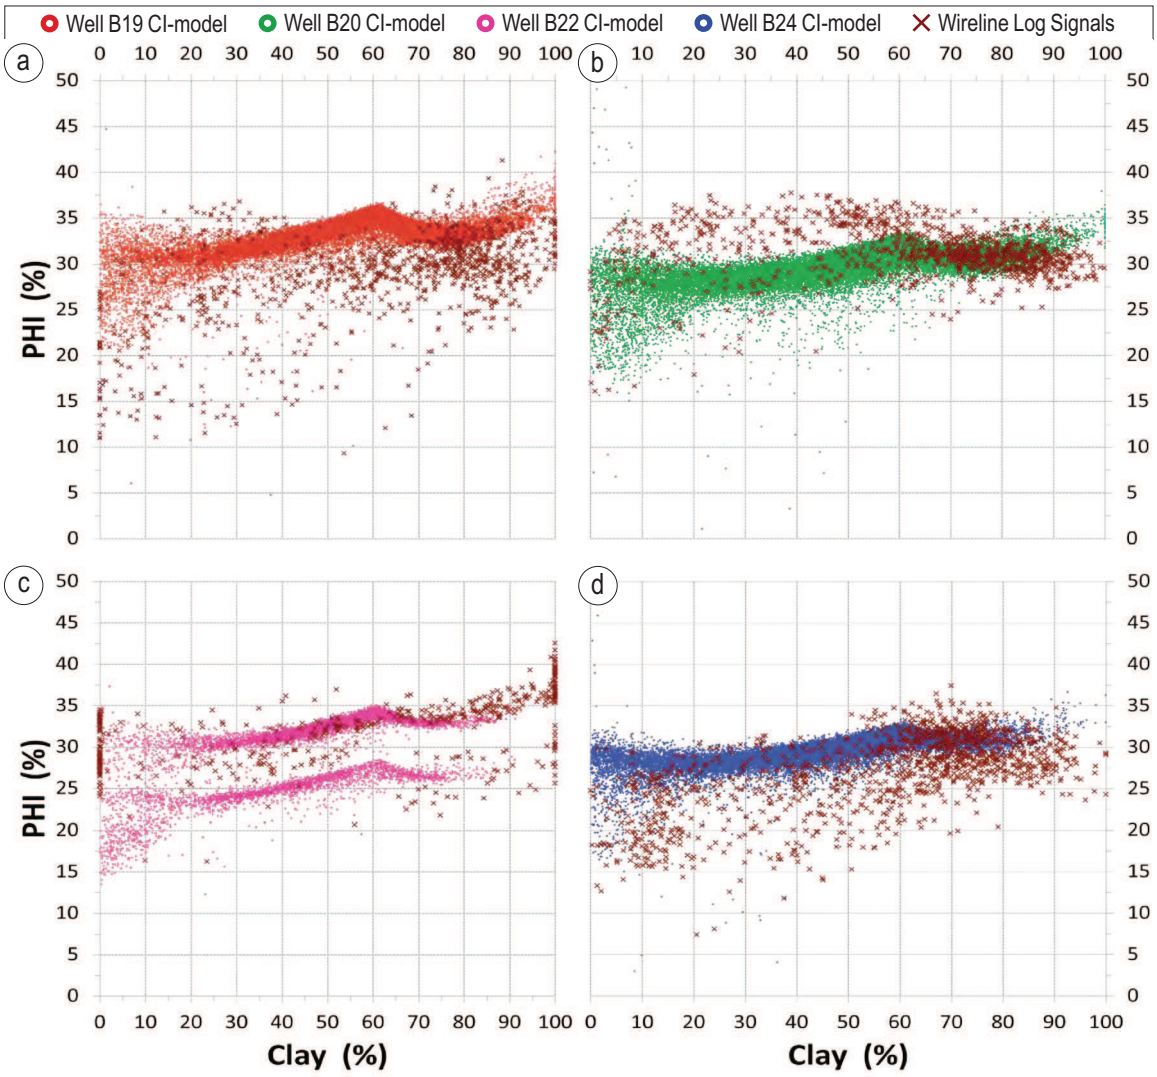

Figure 5–24 Comparison of PHI-model with clay-model results. This plot has been chosen to compare the data ranges with PHIND vs. VSH data from wireline logs that cover the cored intervals. (a) Well B19, (b) B20, (c) B22, (d) B24. Note that wireline log signals at this stage are not yet harmonised (see Chapter 5.3). See Figs. 7–26 to 7–29 for calibrated porosity data.

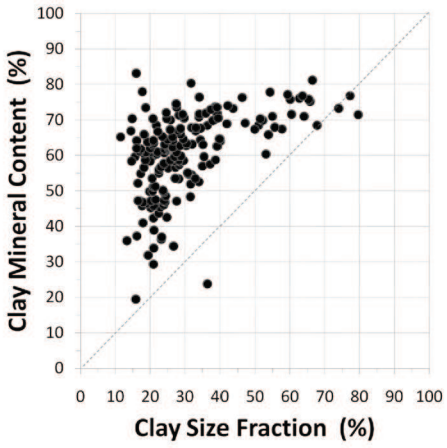

Figure 5–25 QXRD results from the mudrock database imply that clay mineral content has the tendency to exceed the clay size fraction.

tion has yet been performed between the wells (subject to Chapter 5.3). Major deviations can be seen for Well B20, but for the remaining wells discrepancies between modelled and wireline data will be an issue of scale/resolution as well as a proposed mismatch between clay grain size fraction (<2µm) and clay mineral content (Fig. 5–25). However, potential property discrepancies between XRD and sedigraph subsamples from a heterogeneous core plug restricts this kind of data integration (see Chapter 1.3).

The applied grain size and porosity model from core images is considered valid for the property ranges of the analysed mudrock core samples. Applications to sands is restricted by missing input data and their potential to acquire dark coatings that are incompatible with the herein proposed approaches.

5.2 Core facies evaluation

Depth-independent parameters such as high-resolution grain size logs may provide powerful information to perform a coherency assessment of the predefined and subjectively allocated lithofacies in Figure 5–3. In other words, the rock property propagation along photographed core sections in Chapter 5.1 can be used as a quality control that ensures consistent facies interpretation and may represent a first step towards an entirely automated recognition of similar lithological units.

Since the error of the CI models remains unconstrained for sandy strata but yet the model picks up a physical signal (variations in both sand content and porosity) from the core images it has been decided to upscale the generated grain sizes to the facies resolution by computing the global average per core facies unit. Apart from accommodating the profound uncertainty issue another benefit of this procedure is that individual facies sections are closer to the wireline log resolution than the original 5mm CIGS raster (Fig. 5–26). This evaluation approach is based on the assumption that predefined facies boundaries truly

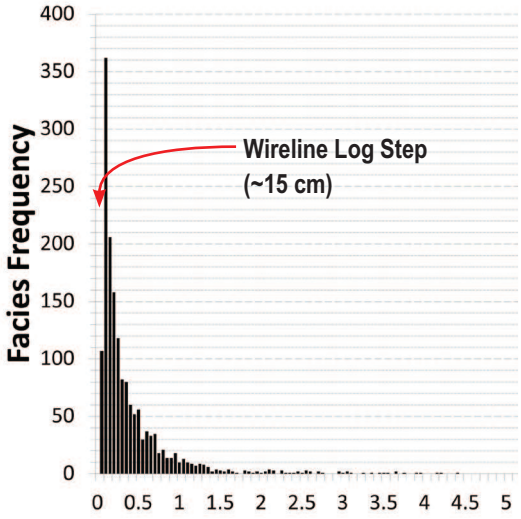

Figure 5–26 Resolution of manually defined facies intervals cumulates around the wireline log resolution (~0.15 m).

discriminate between vertically stacked lithological units.

As mentioned earlier, facies types reflect a blend of prevalent grain sizes (micro-scale) and rock texture (meso-scale). As textural features were already considered during the manual facies allocation (Fig. 5–3) the encountered challenge for calibration of these predefined facies is to apply grain size criteria that yield adequate boundary conditions for the identification of facies that have too faint textures (*i.e.* low contrasts between grain size fractions) to be picked up as a distinctive signal pattern in the wireline log suites (*e.g.*

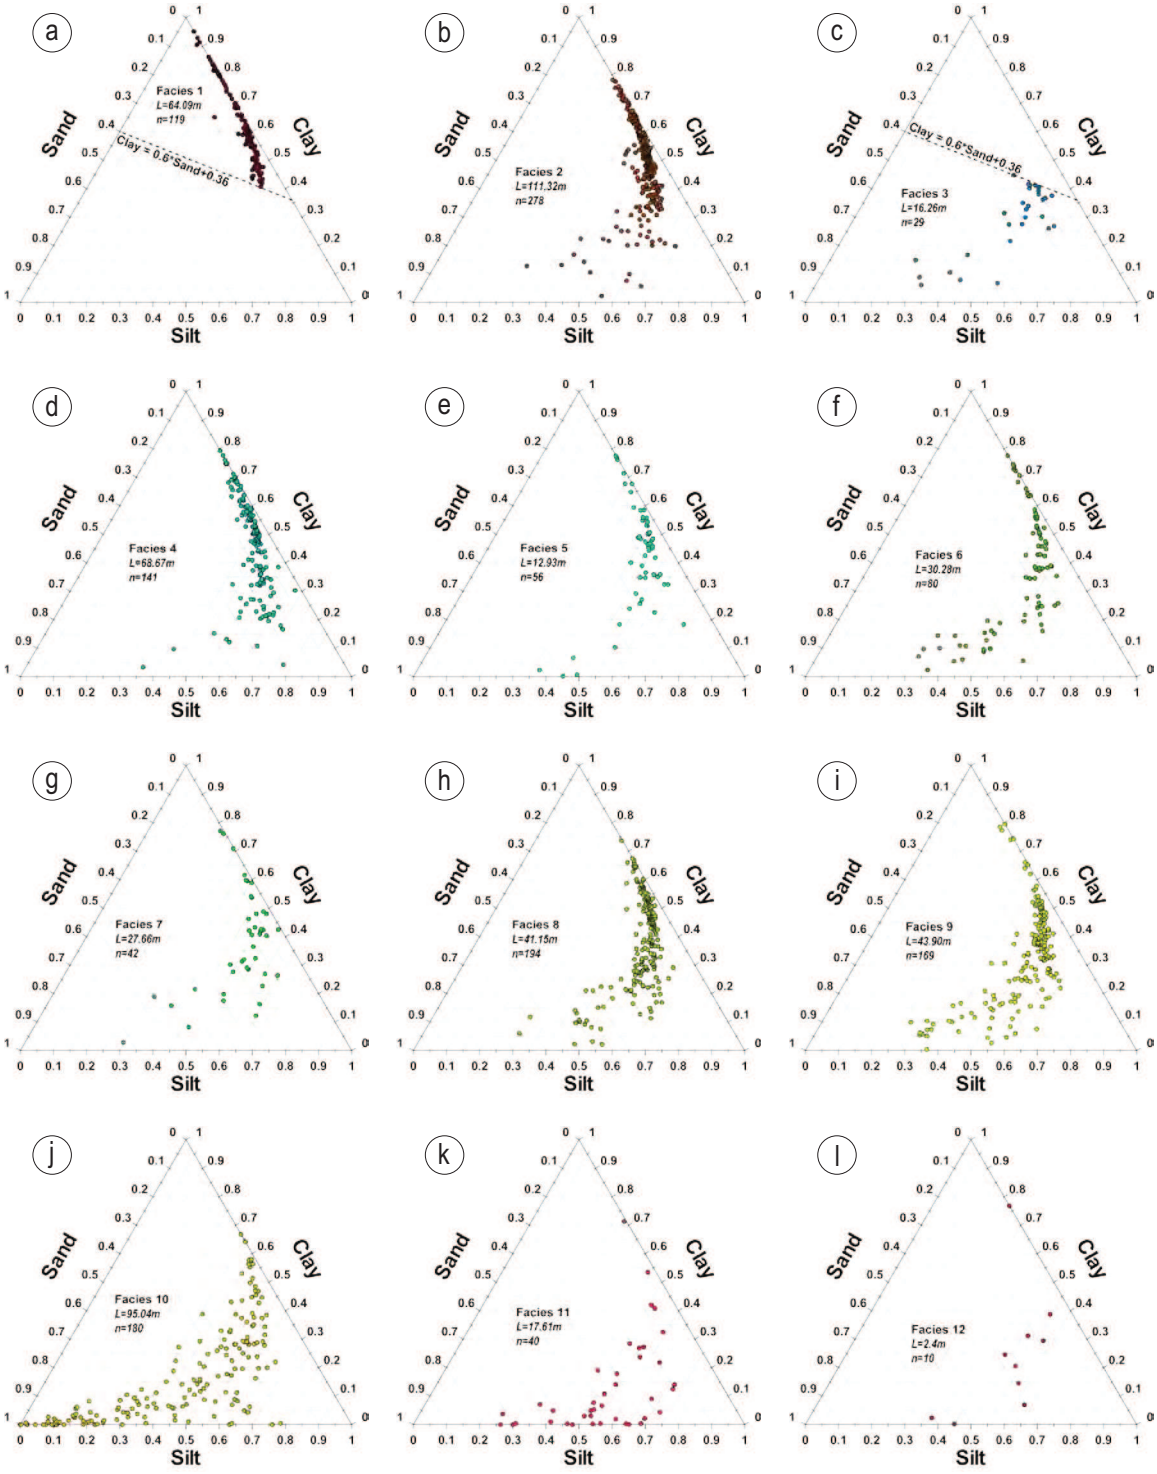

Figure 5–27 Manual facies definition and CIGS output. See text for discussion.

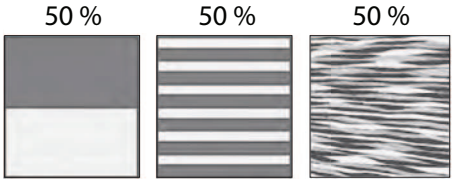
Serra & Serra 2003). In fact, the earlier mentioned continuous transition between different facies allows some clearance in the detection of more or less crudely mis-interpreted textures through the study of mean grain size outliers.

In practice, facies that appear to be dominated by a single grain size fraction (75-80%) have been re-allocated to the respective facies (mudstone, siltstone, sandstone) where necessary. Further, siltstone sections (facies 3) can now be distinguished from clay-dominated mudrocks (facies 1) along the most prevalent gap in the combined grain size diagram (Figs. 5–27a,c).

Although there are already characteristic tendencies in most of the facies-to-grain size plots the result is still not satisfying for a significant fraction of the sand-prone facies (Figs. 5–27e-l, undistinguished) due to unexpectedly large modelled clay contents. It is proposed that this mismatch is partly due to the fact that mean grain sizes do not resolve the texture of a given unit (Fig. 5–28), but mostly due to the dark sandstone issue that may now be considered a global phenomenon rather than being restricted to well B19 alone (Figs. 5–27i-l, undistinguished). It is likely that intermingling of sand slides along the channel axes with thin hemipelagite toppings or other clay-rich levee deposits could explain the unusually low brightness of some of these sections. This discrepancy between visual interpretation of sand-bearing facies and modelled grain sizes precludes a statistical re-evaluation for facies 5 and above. Likewise, core sections suspected to comprise carbonates (facies 13) are also not unconsidered in this assessment because they do not comply with the concept of the CIGS model (Chapter 5.1).



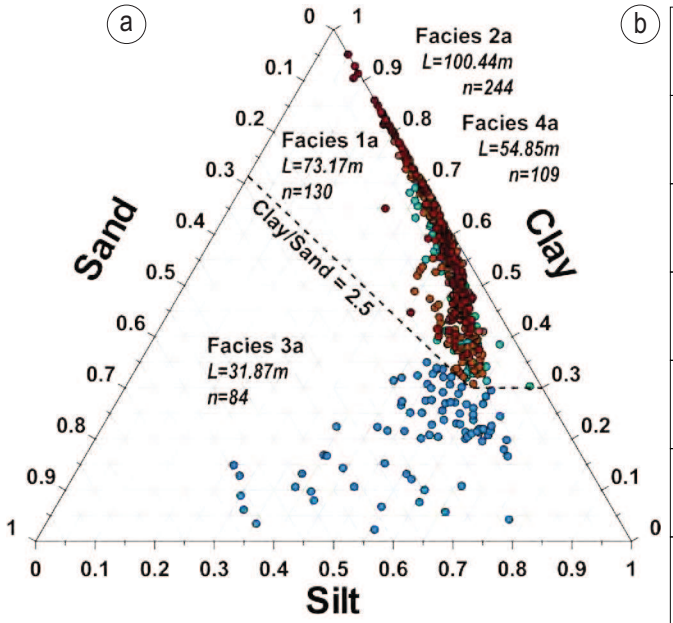


Figure 5–28 Different textures may account for the same bulk lithotype proportion (by courtesy of K. Kurtev with material from Nordahl *et al.* 2008).

More sophisticated algorithms may be capable of further processing the grain size distribution along the entire length of each core image section, picking up recurring patterns and grouping that information to any desired number of lithotypes. However, the applicability of quantitative facies description should be validated on a basic level before it may eventually expand towards more complex and time consuming models. As the sandy facies are not satisfyingly recognised by the grain size model (Fig. 5–27) the initial subjective interpretation of facies 5 to 13 cannot be validated in terms of consistency and reproducibility. Therefore, testing of different facies classifications on the basis of grain size and texture properties for their degree of recognisability in wireline log signals will be entirely restricted to a set of mudstone facies variations (Fig. 5–29) in Chapter 5.3.

The sheer abundance of generated data points allows the unique mudstone definitions

in Figure 5–29 and at the scale given in Figure 5–26, not least because the continuity between grain size end-members precludes the universal and unequivocal classification of siliciclastic sedimentary rocks (Potter 2005).

b

Mudrock Variation	Facies Indices	Facies Description
original	1 2 3 4	homogeneous laminated silt-rich slumped
A	1a ≡ 1-3a 2a ≡ 2-3a 3a ≡ *f*(1,2,4) 4a ≡ 4-3a	homogeneous laminated silt-rich slumped
B	1b ≡ 1a 2b ≡ 2a+4a 3b ≡ 3a	homogeneous lamin./slumped silt-rich
C	1c ≡ 1a+4a 2c ≡ 2a 3c ≡ 3a	homog./slumped laminated silt-rich
D	1d ≡ 1a+2a+4a 3d ≡ 3a	claystone siltstone
E	1e ≡ 1+2+3+4	mudstone

Figure 5–29 (a) Example plot for the alternative mudrock facies classification 'Variation A'. The siltstone boundary (clay/sand ratio < 2.5 or clay content < 30%) and claystone boundary (> 80% clay content) is consistent throughout all proposed variations (b). Variations B-D reflect a systematic fusion of facies populations as defined in variation A.

5.3 Wireline facies propagation

In general, one of the most fundamental requirements for any kind of data integration is that the physical relation between the signals of interest is strong enough to reproduce one signal from the other and *vice versa*. It has been demonstrated in the previous section that grain size and core image data from mudstone intervals reflect these prerequisites to a reasonable extent. This outcome encourages to further investigate whether facies re-evaluation based on the CIGS output leads to significantly enhanced ANN propagation of lithological facies profiles along the wireline log sections.

In the petroleum industry, core recovery from deep boreholes is usually conducted within the reservoir and its immediate vicinity. However, since core texture and laboratory analyses provide the most detailed information on the smallest conventional scale it is desirable to generalise or upscale the lithological information and propagate it along the entire stratigraphic section where physical/chemical borehole information has been gathered. These wireline and mudlogged intervals in the western Nile Delta province comprise up to two kilometres of continuous measurements per well, while cored intervals range only from 60 to 350m. In this study, the aim of lithofacies-to-wireline log integration is particularly focused on obtaining a complete lithological characterisation of the cap rock

intervals where only little core information has been gathered.

Regressions between wireline log signals and facies type are multi-dimensional depending on the variety of log signals and facies used for the classification. Moreover, wireline logs represent continuous quantitative data whereas facies are forced into a subjective framework of usually not more than 10-20 qualitative classes. These structural discrepancies between the two input data types require the application of an artificial neural network (ANN). Suitable ANNs can be trained to discriminate the input facies according to their respective ranges of wireline signals in a multi-dimensional space. Here, the number of dimensions used for the regression is equivalent to the number of input log signals. Once the empirical link between facies and wireline signals is carefully calibrated, the trained ANN model can be propagated along the non-cored borehole intervals to determine the most probable output facies. A particular strength of ANN applications is that a sufficient quantity of training data will re-associate the few facies that were manually ascribed to the wrong category.

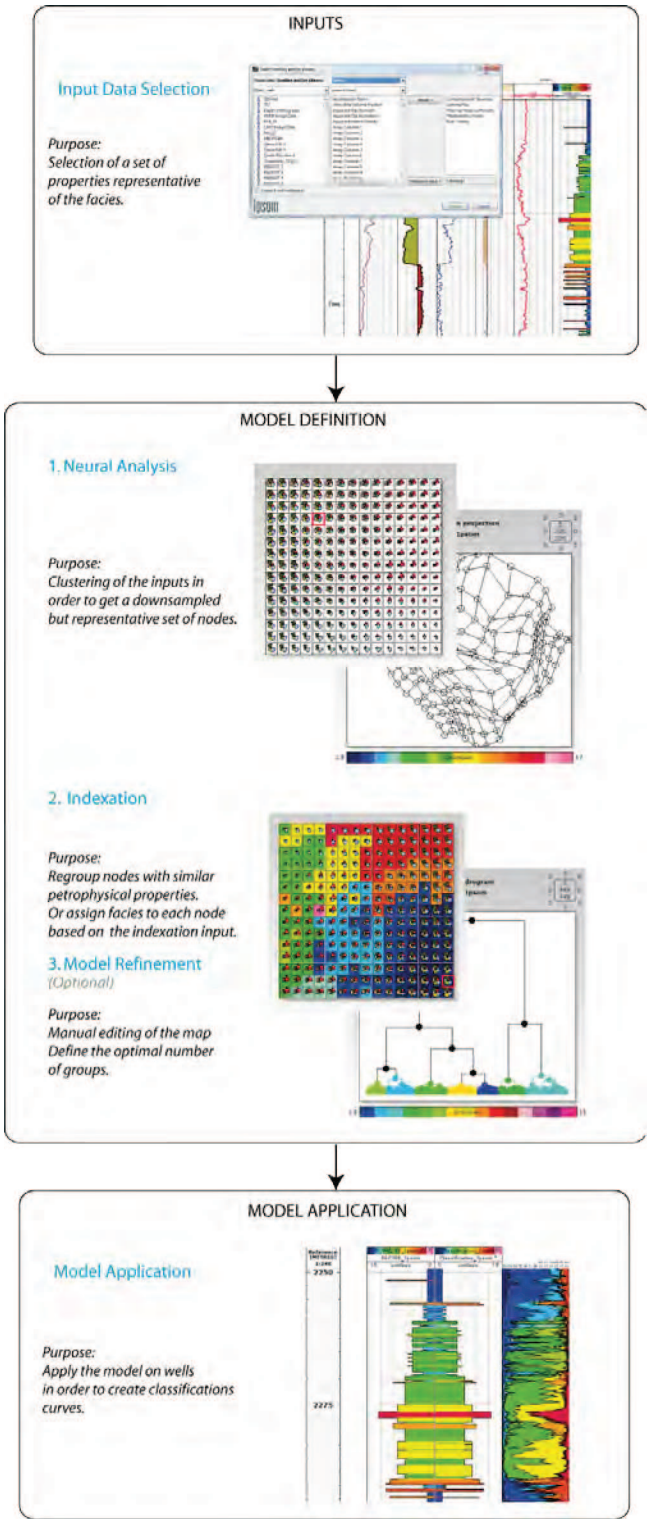

Figure 5–30 Ipsom workflow for supervised lithofacies recognition from any combination of wireline log signals (source: TechLog help file).

ANN training in this study has been performed by the *Ipsom*-module of the petrophysical software package TechLog 2010.1.3 (Techsia/Schlumberger). Ipsom is particularly designed for geological interpretation of well log data and facies prediction based on the principle of self-organising maps (Kohonen 1982 2001). A generalised workflow from the TechLog help file is shown in Figure 5–30.

However, calibration of the Ipsom

model is a difficult task. Firstly, the assumption that each manually defined facies can be uniquely picked up by a range of wireline signal combinations may not be true. Secondly, discrepancies between input and output facies within the core interval may not always be subject to a wrongly assigned input classification (*e.g.* atypical pore fillings, borehole wall disruptions, etc.). Thirdly, the scale over which facies occur and log signals are integrated may be different (*e.g.* Fig. 1–14). Here, the general logging step of about 15.24 cm may lead to boundary discrepancies between input and output facies of up to 7.12 cm because down-sampled facies boundaries fall right between the log steps (Fig. 5–31). Likewise, a strong facies contrast in the vicinity of a log signal may lead to a wrong classification because the logged property is a product of signal interference between the adjacent lithotypes.

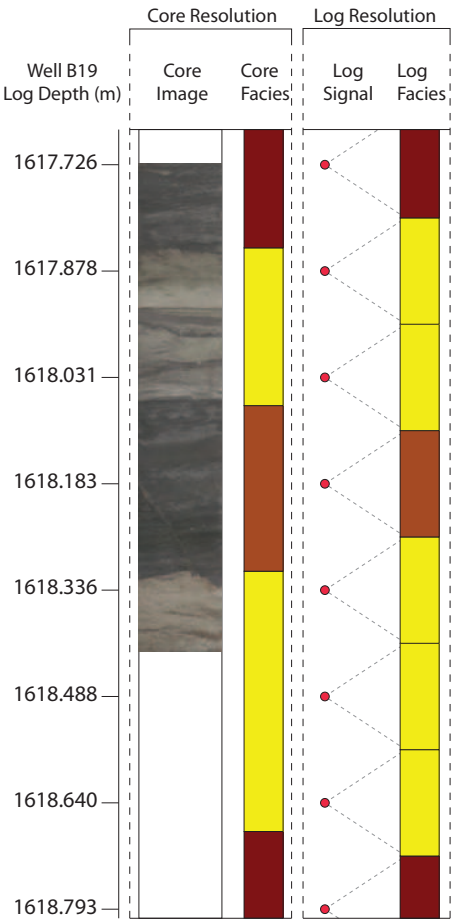

Figure 5–31 Resampling of initial facies boundaries to the wireline log scale may induce boundary discrepancies of up to 7.12 cm, which is half the log step (15.24 cm).

Log signal processing Apart from all the above restrictions it will clearly be a benefit for the sake of quality and coherency if the ANN training was performed on the bulk of the data set rather than individually for each well. Global ANN training compensates for facies that are rare or absent in one well compared to the others (Fig. 5–32).

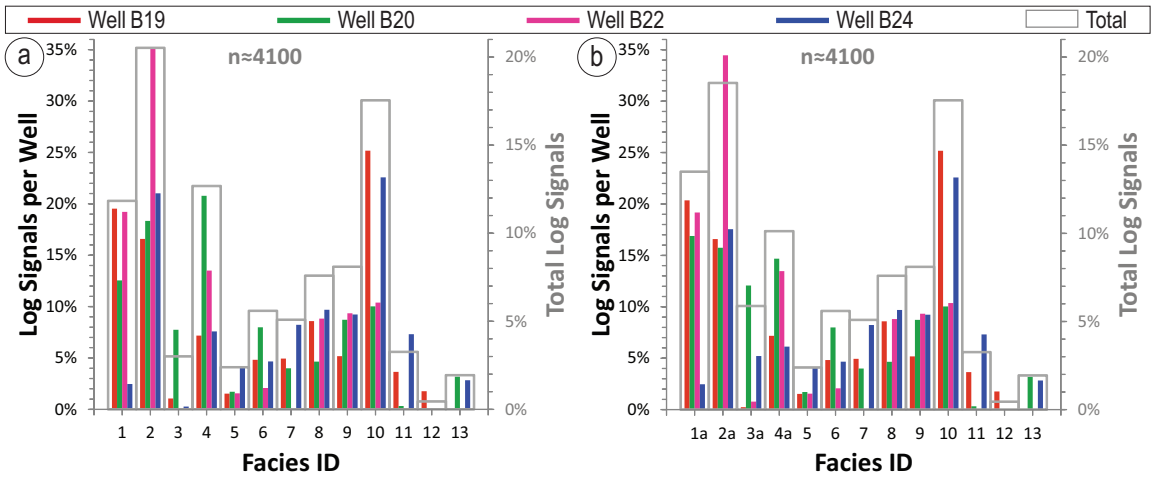

Figure 5–32 Distribution of wireline log signals that are associated (a) with original facies and (b) with mudrock variation A (see Fig. 5–19 for different mudstone facies variations). The latter has a more balanced log coverage (for the benefit of facies 3a) that may lead to an improved ANN training.

Treating the log signals of different wells in a single ANN training session inevitably requires signal harmonisation, *i.e.* correction for fundamental signal differences as a consequence of borehole environmental factors and individual logging device calibration (K. Kurtev personal communication). In the four wells investigated those environmental differences are considered negligible since they used the same oil-based drilling fluid and are run by the same contractor. However, a direct integration of wireline data from different wells is not feasible because the sensitivity functions of the applied tools are not preserved.

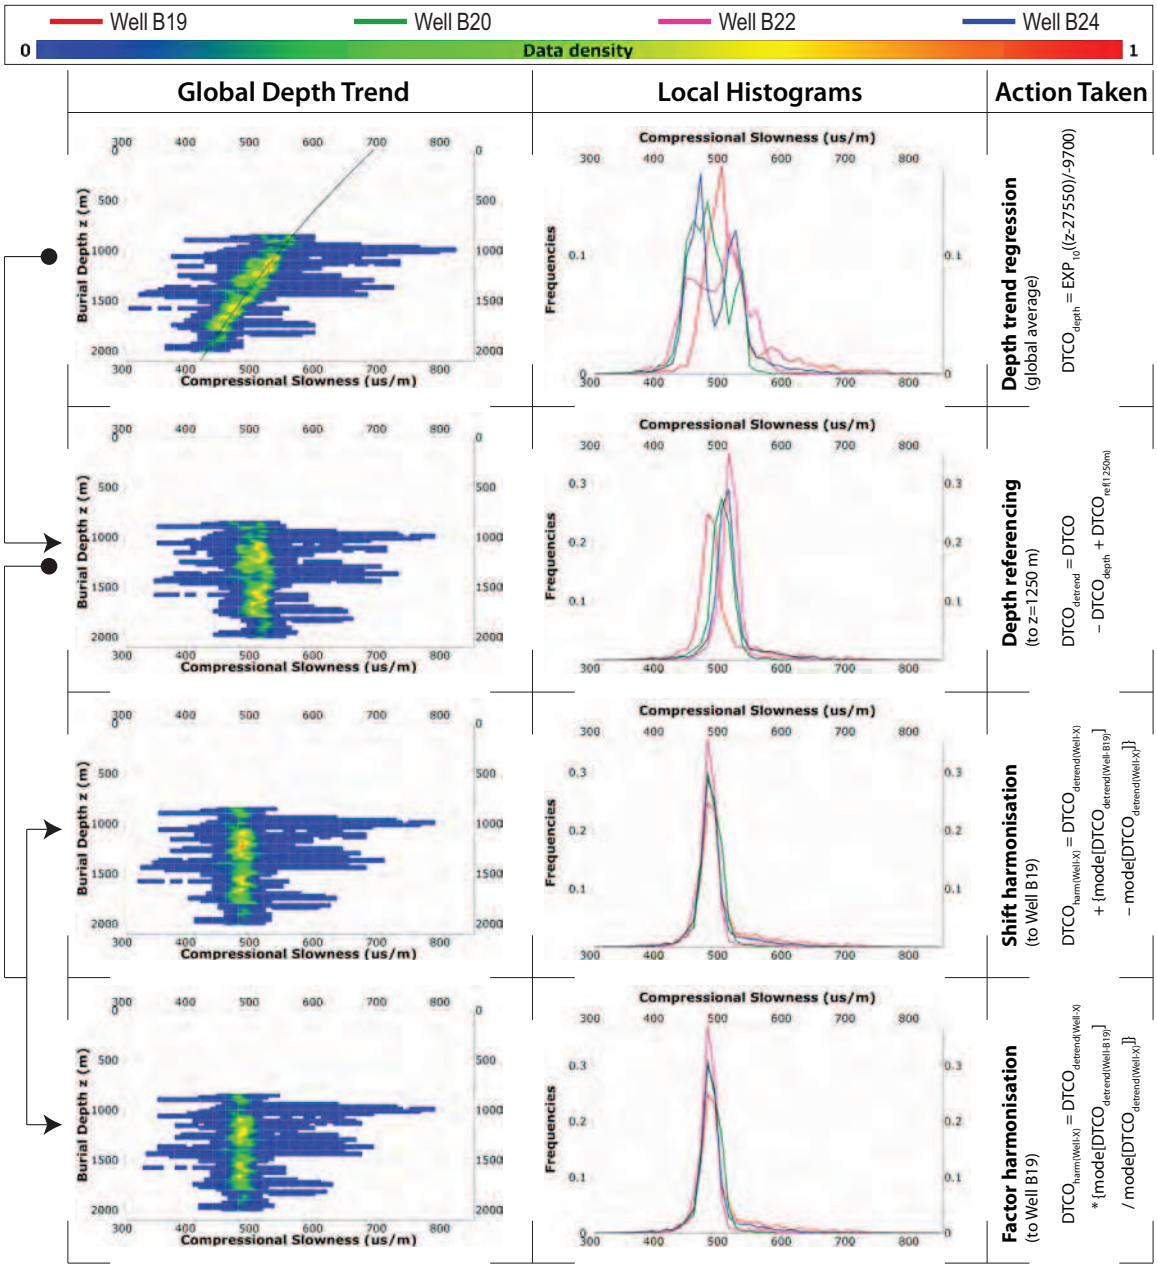

Figure 5–33 Detrending and two proposed harmonisation procedures (signal bulk shift vs. factor-matching) for the compressional slowness (DTCO) logs of different wells. Trends and histograms are specific to the log signal type but the applied formula structure is principally the same (see Appendix B for the entire log range). Reference burial depth for the detrended log signals was chosen to be at 1250m and the detrended signal distributions from Well B19 served as harmonisation reference for Wells B20, B22, and B24. us/m ≡ µs/m

An alternative workflow would incorporate the adjustment of signal intensity distributions between similar lithological intervals from different wells. However, the available biostratigraphic and sequence stratigraphic units (data not shown) indicate strong thickness variations from one well to the other as a function of their geographical position. In addition, shifts in log signals with increasing burial depth as a result of compaction further handicaps trustworthy manipulation of raw signal distributions.

In this study it is the depth trend of log signals that poses the most suitable opportunity for log harmonisation. Since facies do not change their macroscopic appearance during shallow burial it is important to remove any depth-related signal change prior to facies mapping and especially prior to propagation of wireline facies along a 2 km vertical profile (Figs. 5–33 and 5–34).

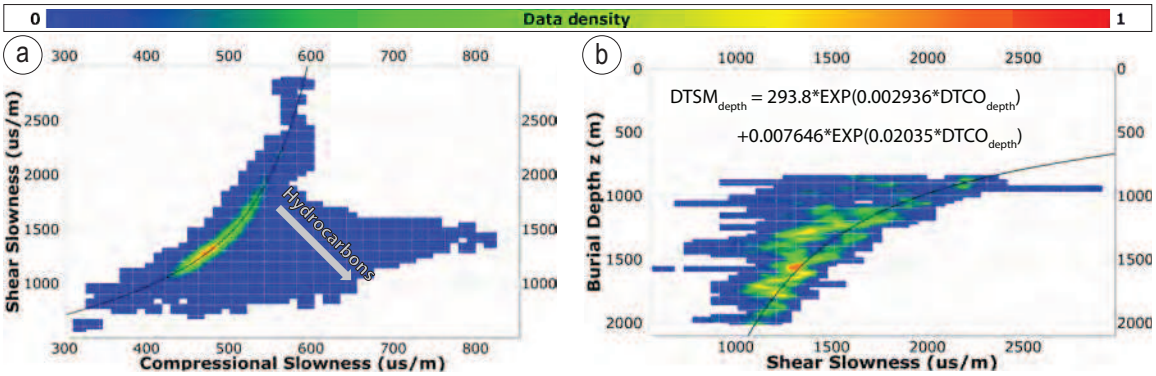

Figure 5–34 (a) The original velocity ratio is substantially affected by hydrocarbon saturation that (b) leads to ambiguous depth trends particularly in terms of the original shear slowness. Detrending and harmonisation for shear slowness were therefore conducted under preservation of the prevalent velocity ratio (see also Appendix B). us/m ≡ µs/m

The quality of the de-trending and harmonisation workflow is facilitated by a relative monotonous burial history devoid of detectable uplifting events (Fig. 1–2), the general absence of severe overpressure zones in the post-Miocene (*e.g.* Figs. 7–26 to 7–29), lack of substantial diagenetic cementation (chemical compaction), and the fact that the wells under consideration were drilled close to vertical (inclinations below 5°). The reference for wireline log detrending was chosen to be within a common burial depth where log signals of the individual wells are close to their baseline (1250 m). An alternative decompaction to surface conditions (0 m) was discarded due to the lack of associated calibration data.

ANN training Prior to the ultimate ANN calibration a series of training sessions were run in order to define the mudrock facies that have the highest recognisability on wireline logs. Further, the same study would help to identify the quality of performed log signal transformations as described in the previous section.

Input data for quality control are seven common log signals – both original and harmo-

nised – of the four wells under consideration plus their allocated and depth-shifted facies intervals, including all the variations in mudrock classification listed in Figure 5–29b. Each data combination was run in bulk sessions with equal Ipsom settings. Previous studies showed that a 12*12 grid size Kohonen map is suitable for the applied data set (7 log signals of equal weights ≡ 7 dimensions with ~4100 data points each). During training the respective facies classifications supervise the self-organised log signal mapping.

As for the wireline log manipulation, factor-harmonised signals gave the best recognition of the bulk facies (Fig. 5–35). This observation is independent of the variations in mudrock classification and almost entirely due to enhanced correlation factors for bulk density (RHOZ) and porosity (PHI), both largely insensitive to pore fluid variations. However, differences in mudrock classification are hardly picked up since only a small proportion of the bulk interval was altered. The only clear statement in terms of mudrock classification is that those entirely based on mean grain size criteria (variations D and E) are certainly not as suitable for ANN recognition as mixed grain size/texture based definitions (remaining variations).

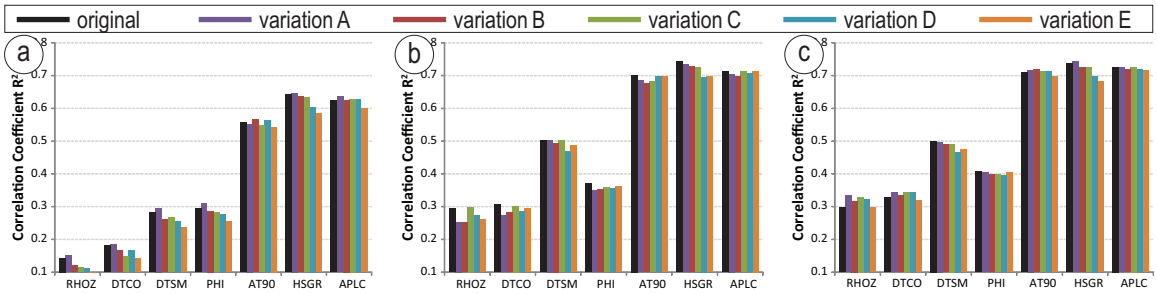

Figure 5–35 Wireline log-to-facies correlation for (a) the raw log signals, (b) shift-harmonised signals, and (c) factor-harmonised signals. The latter are apparently most suitable for ANN training since they yield the highest correlation factors independent of variations in mudrock facies classification. RHOZ: bulk density (g/cm³), DTCO: compactional slowness (µs/m), DTSM: shear slowness (µs/m), PHI: porosity (v/v), AT90: deep resistivity (Ωm), HSGR: gamma ray (gAPI), APLC: neutron porosity (v/v).

The most suitable mudrock classification must be determined via a second study with blanked-out non-mudrock sections and factor-harmonised log signals (Fig. 5–36). Variant C apparently drops out of the competition, *i.e.* homogeneous and slumped strata can be distinguished from wireline logs, at least to certain extent. Also, slumped and laminated rocks (variant B) do not form a common wireline facies. Nevertheless, the siltstone facies as defined from the mean grain sizes (variant A) yield an improved recognition particularly in terms of bulk density and gamma ray (HSGR). In

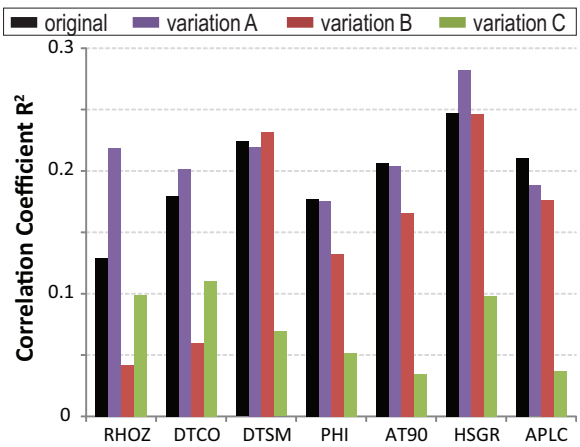

Figure 5–36 Mudrock variation A yields the highest correlation coefficients and is hence most suited for wireline facies training.

conclusion, mudstone classification A in conjunction with depth-detrended and factor-harmonised wireline log suite will yield the most accurate wireline facies.

However, since there is hardly a 100% fit between input (core) facies and output (wireline) facies – otherwise the ANN module would be needless since in that case lithotype recognition would be a rather straightforward task – the fields of the Kohonen map require a specific indexation method that determines which input facies has the largest overlap with the allocated log signal dimensions (Fig. 5–37). The quantitative classification yields a probability function and is therefore the most suitable indexation method in terms of quality control.

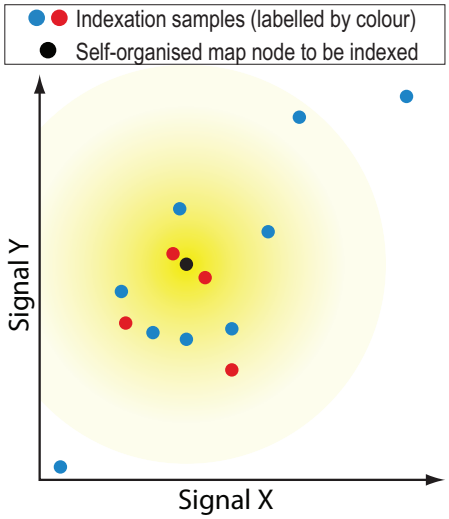

Figure 5–37 The Ipsom module provides three different indexation methods. Minimal distance: For each node of the self-organized map, the label assigned to the node will be the label of the indexation sample that has the closest properties (the illustrated note will be red). Majority vote: All the samples similar to the node are taken into account and the majority label is assigned to the node (the illustrated note will be blue). Quantitative classification: The probability of each label is computed from the distance between each sample of the indexation data and the node. The highest probability defines the label of the node (the illustrated note will be red). Examples and explanations according to TechLog help file.

Calibration of the Ispom ANN with the identified input data yields a Kohonen map that shows a spatial progression from coarse to fine grained facies while carbonates have clearly distinctive petrophysical characteristics (Fig. 5–38).

Still, the absence of 1:1 correlations between log signals and facies types precludes a 100% reproduction of the input core facies (Fig. 5–39). These non-correlations result from spatial overlapping of the facies-attributed data clusters in a multi-dimensional log signal space and are reflected in a probabilistic attribution of the output facies (Fig. 5–40).

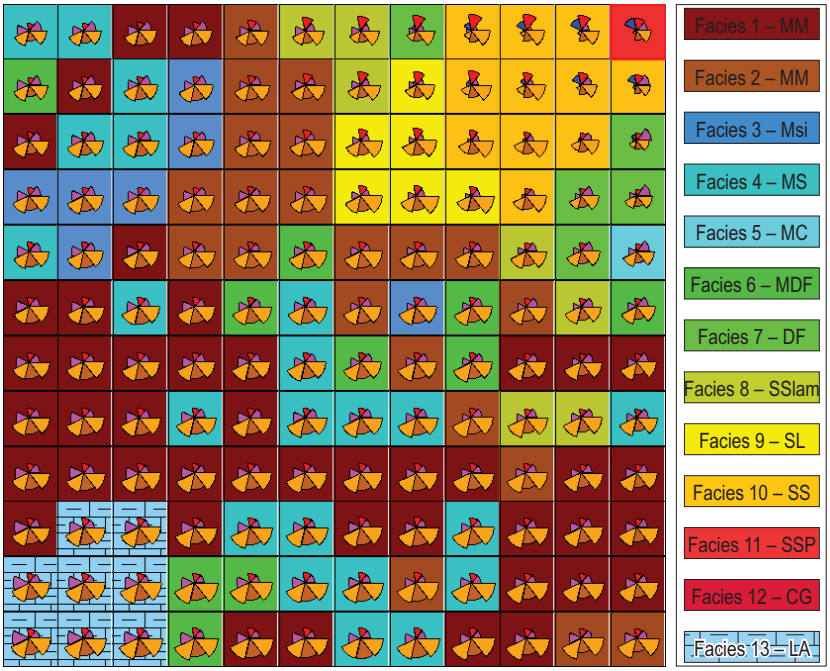

Figure 5–38 Self-organised map for facies variation A and factor-harmonised wireline log signals shows sandy and carbonate facies in opposite corners. They are mediated by a facies progression associated with increasing fine grain size fraction (top right towards bottom left). Some muddy debris flows (facies 6) appear to be notably associated with carbonates. Log signal ranges per region are illustrated by (undistinguished) 7-fold rose diagrams.

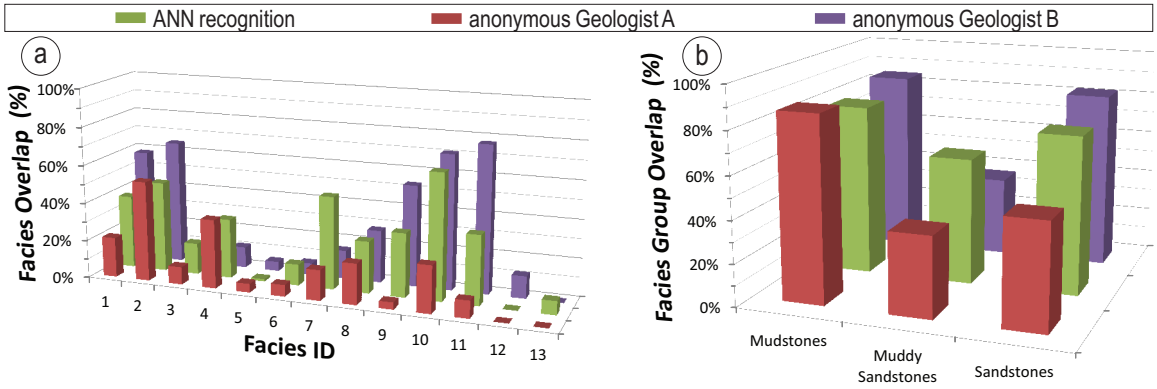

Figure 5–39 (a) Reproducibility of the calibrated lithofacies by ANN recognition is in the same error range as the matching of core facies interpretations from different fellow geologists (anonymous colleagues). The strongest discrepancies between input and output facies are clearly within the transition range between mudstone and sandstone end-members. (b) Certainly, the further we merge similar facies into groups the higher the reproducibility. The illustrated example lithologies represent the following facies groups: *Mudstones* comprise facies 1-6, *Muddy Sandstones* comprise facies 7-9, and *Sandstones* comprise facies 10-12.

In other words, such ANN applications allocate output categories (wireline facies) according to their highest ranked similarity in a quantitative database (seven log types) to the allocated input data (core facies). Since those similarities are expressed as probabilities it is optional to apply a lower limit cut-off for quality control as a post-processing measure. Considering the distribution of probabilities in Figure 5–40 one understands that there are by nature a lot of borderline decisions in facies interpretation, both from geologists and software. As for now, the generated probabilistic geological profile will suffice for contextual evaluation of gas geochemistry and saturation.

Synopsis of Chapter 5 In an unique attempt to validate manual and thereby subjective lithofacies allocations to core images a subset of rock sample properties such as grain size fractions and porosity from Chapter 4 were successfully modelled using quantitative core image properties. However, model validity appears to be restricted to clay-rich lithofacies due to both (1) absence of calibration data for sands and (2) occurrence of abnormally dark sandstone units.

Propagation of various mudstone facies re-definitions based on both manually allocated textures and average grain size fractions resulted in the most distinguished mudstone wireline facies recognition from a commercial ANN application. Integration of the wireline facies profiles of the logged borehole intervals with gas geochemical and saturation data in Part IV must be conducted with care because reproducibility of the (yet calibrated) input facies is as ambiguous as reproducibility from fellow geologists. As a consequence, the initially defined 13 different facies types were merged into 3 simple facies groups (mudstones, muddy sandstone, and sandstones) in order to increase reliability of the lithological wireline profiles to 60-80%.

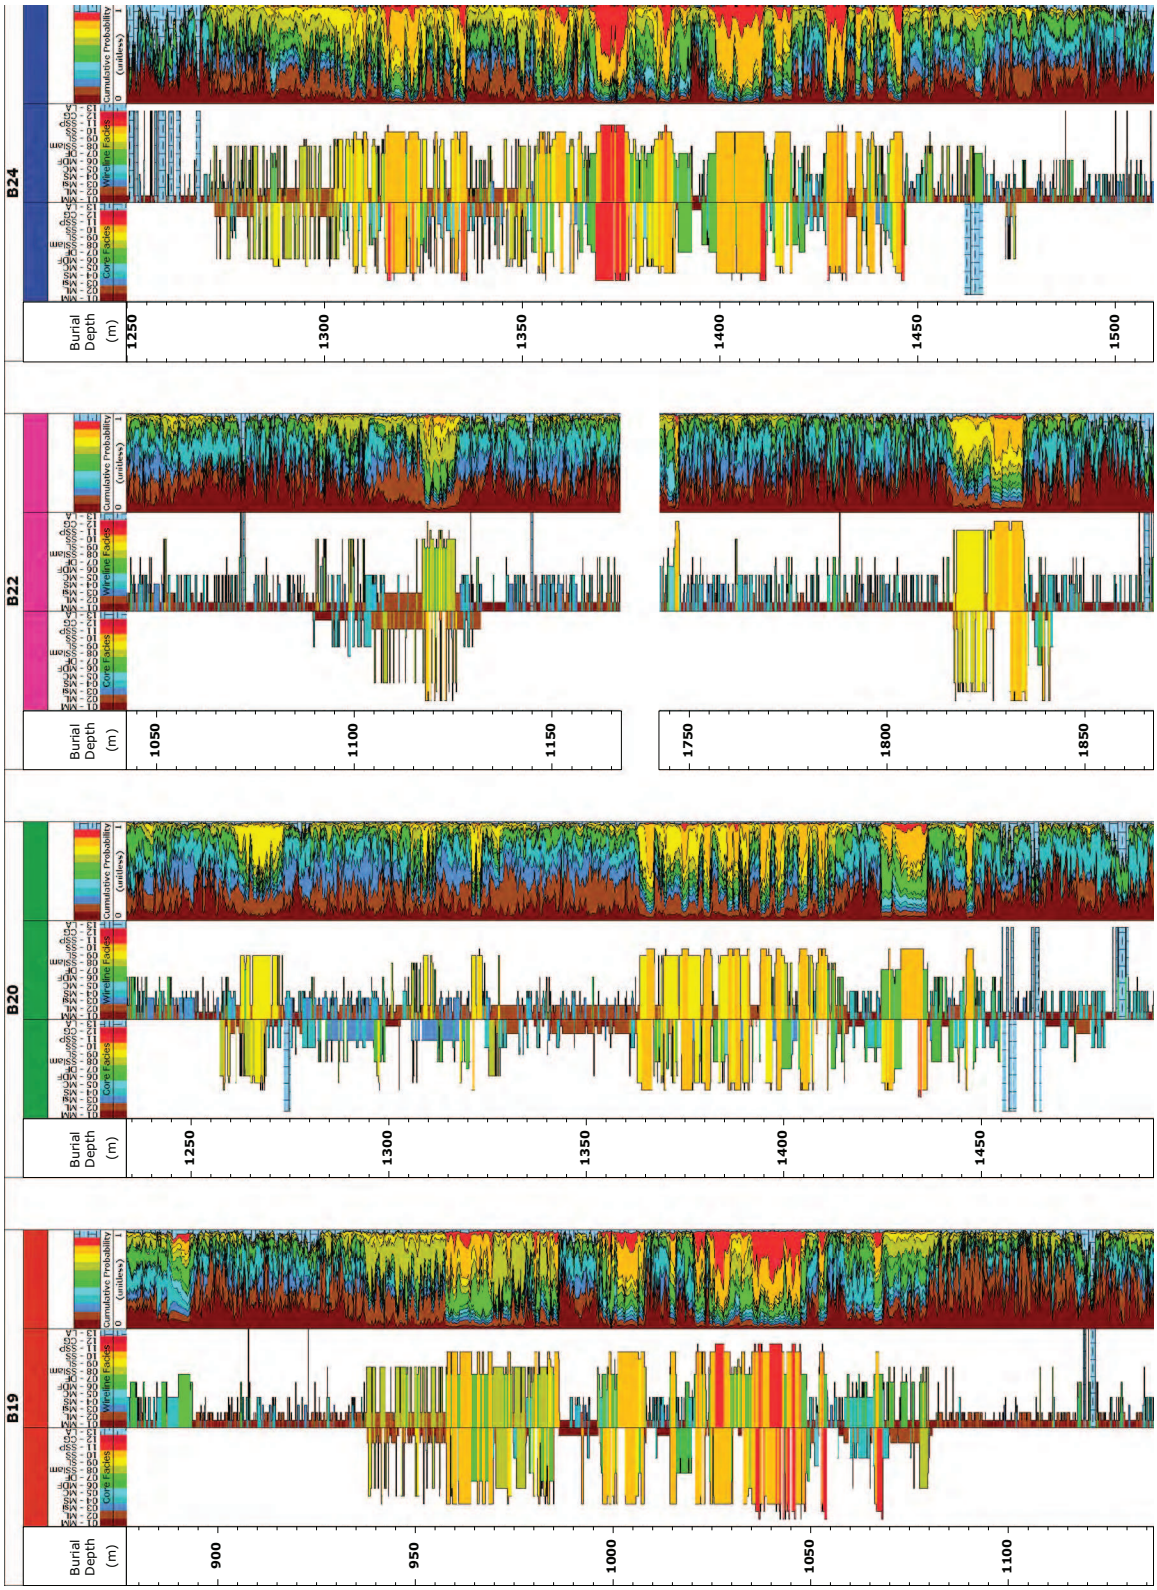

Figure 5–40 Comparison of input (core) facies and output (wireline) facies and associated cumulative probabilities. Input facies were left blank where core images are not preserved and microresistivity borehole images (OBMI) did not allow interpretation. Some mudrock sections (base B19), sandstone sections (top B20/B24), and carbonate sections (top B20, base B24) were not reliably reproduced. These mismatches could be due to borderline texture interpretation in case of mudrock facies (especially slumped vs. laminated), certainly inaccurate core shifting in case of B20's cap rock section (ambiguous shifts due to low COGR and OBMI amplitudes), and high mud-content as well as limited training input in terms of carbonate facies (Fig. 5–32). The latter constraint is transmissible to facies 12 (conglomerates) which lead to complete indexation failure. Further, debris flow (facies 7) and sandstones facies (facies 9 to 11) seem to be compatible in their log signal range, possibly due to poor discrimination of primary and reworked ("dark") sandstones during manual core image interpretation. The complete output profiles are attached in Appendix C.

Part III – Detecting a Free Gas Phase

So far it was dealt with the genetic history of *in situ* drilled and *ex situ* sampled gases (Part I) as well as the lithological medium that may constrain or foster the movement of hydrocarbons in the subsurface (Part II).

However, at this stage it is neither comprehensible at which compaction state a sampled gas has been emplaced nor if any of the previously identified secondary chemical fingerprints were acquired during migration (*e.g.* through the reservoir) or entrapment (*e.g.* inside the seal section).

In such physical sense, the question of present day gas seepage through the pore network inevitably calls for quantification of the pore fluid phase volumetrics. This thesis part deals with the concepts (Chapter 6) and physical detection (Chapter 7) of two-phase flow systems across fine-grained sedimentary rocks, providing the final piece of the migration puzzle unravelled in Part IV.

Chapter 6 How fluid volumes control migration rates

The volume fraction of free hydrocarbons in a water-wet porous medium – hereafter referred to as (gas) saturation – is a key parameter for seal risk assessment because it controls whether isolated gas bubbles connect to a continuous filament that supports Darcy-flow and consequently seal breach (*e.g.* Neglia 1979). Accordingly, detection of hydrocarbon saturation will unravel the predominant present-day migration mechanism with implications on reservoir leakage rates through the cap rocks under consideration – given the spatial constraints of the boreholes with respect to reservoir dimensions.

Advection vs. diffusion Experimental studies from Schowalter (1979) have shown that the percolation (or displacement) threshold of mudstones can vary between 4% and 17% (Fig. 6–1), with an average of 10% being the most suitable approximation up to date (Nabawy *et al.* 2009). In other words, a water-wet cap rock requires 4-17 vol.% of free petroleum in order to establish a continuous filament, allowing leakage via bulk flow in

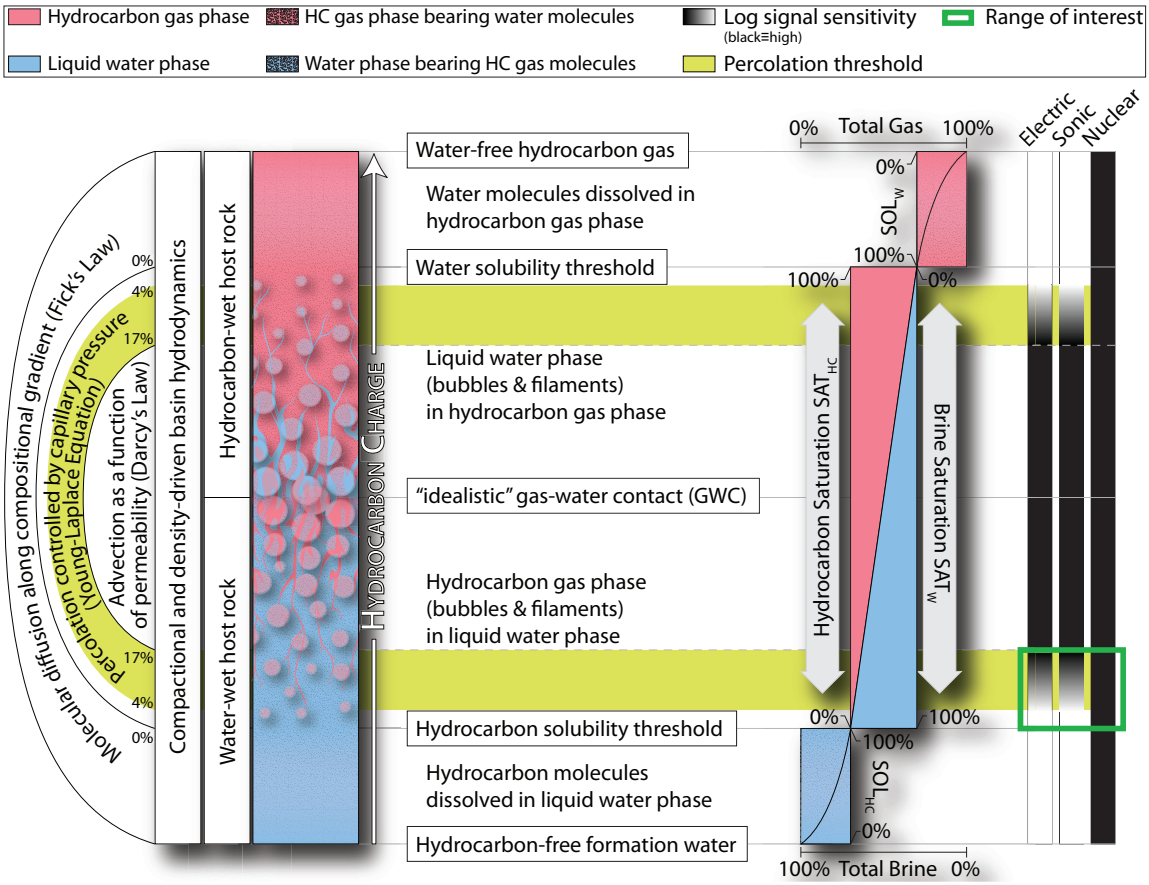

Figure 6–1 Hydrocarbon migration scheme through porous media as a function of total gas concentration. Total gas is the sum of gas dissolved in water (SOL_{HC}) and free gas (SAT_{HC}) minus the water molecules dissolved in free gas (SOL_W). Accurate determination of low gas saturations facilitates conclusions about the predominant migration mechanism. The most reliable input parameters for low saturation models at a borehole scale are wireline logs that stimulate nuclear interactions (neutron & gamma) since they are comparably indifferent to pore phase behaviour but respond to the total gas concentration. Low saturations (green box) in the non-reservoir are of particular interest in this study because they control the migration mechanism and therefore leakage rate of hydrocarbons through the pore space of mudstone seals.

terms of Darcy's Law. Accordingly, only if that is the case the rate of loss will be a function of the relative permeability of the cap rock.

However, the cap rock will act as a capillary pressure seal if saturations remain below the percolation threshold and isolated hydrocarbon "bubbles" are consequently subject to capillary entrapment. Associated column heights are in this situation controlled by the relative strength of two opposing forces: (1) upwards directed buoyancy pressure of the hydrocarbon column at the top of a trap, and (2) downwards directed capillary entry pressure (CEP) in the interconnected pores of the overlying cap rock (Schowalter 1979). Unless the spill point of a filling trap is reached beforehand, the buoyancy of a growing hydrocarbon column within the reservoir may eventually overcome the CEP at the reservoir/seal interface and hydrocarbons leak upwards into the cap rock section. Capillary failure increases the hydrocarbon saturation within the cap rock pore space and will ultimately lead to the establishment of Darcy flow along continuous filaments of hydrocarbon phase, *i.e.* seal breach. In addition, hydrocarbon gas bubbles nucleate easily on the solid pore surface even inside a mudrock seal section since capillary pressure has a physical sense only where two phases exit (Sheng *et al.* 1999).

The ability of rocks to resist internal expansion may lead to a high internal gas bubble pressure that counteracts the chemical force exerted by the dissolved gas gradient near the bubble surface (Algar & Boudreau 2010 – and references therein). This means that the bubble pressure can rise above the pressure of the surrounding pore fluid and is controlled by the degree of supersaturation and matrix shear strength. If supersaturation (and therefore gas source strength) is high the internal bubble pressure may eventually rise above the shear strength of the surrounding rock and induce fracture propagation. A no-growth condition is subject to lower ratios between supersaturation and rock strength that foster an equilibrium between bubble pressure and phase gradient before the point of shear failure (Gardiner *et al.* 2003). Either way, filament formation within mudstones from progressive exsolution of an internal gas source – such as scattered kerogen in a source rock or methanogenesis in a shallow cap rock (England & MacKenzie 1989, Algar & Boudreau 2010) – would be inhibited without microfracture propagation. Low overpressures in the relatively shallow Nile Delta Pliocene – consequently – preclude microfracturing as will be demonstrated in the next chapter.

In non-fractured mudrocks, migrating thermogenic gas from external sources may bypass *in situ* microbial gas bubbles that are entrapped in interstitial pore water via the structural water network (Fig. 6–2; Whiticar 2002). This observation, described as "hand-shake migration", supports the argumentation of Horvitz (1985) that migrating gas is preferentially adsorped to clay mineral surfaces relative to *in situ* microbial gas.

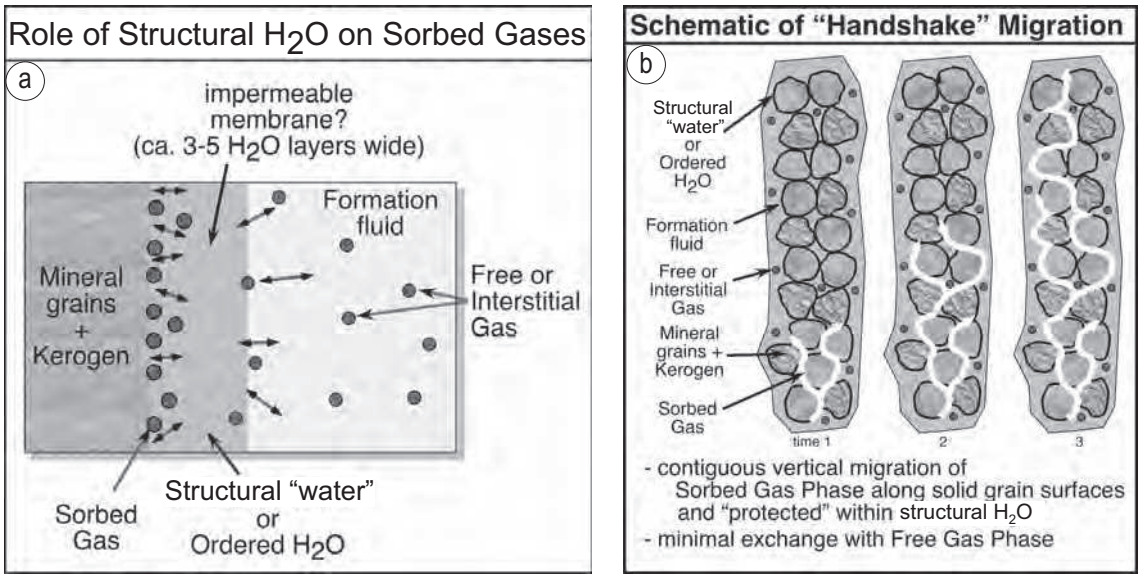

Figure 6–2 Predominantly pristine thermogenic fingerprints of gases formerly sorbed to rock matrix surfaces suggests that the structural water interface may act as a physical barrier between sorbed thermogenic and interstitial microbial gas. (b) The presence of these sorbed *ex situ* gases could be explained by intra-membrane movement termed "handshake migration" (from Whiticar 2002).

Without free gas there would be background phenomena such as slow diffusion of the dissolved phase (*i.e.* hydrocarbons) and compactional flow of the host phase (*i.e.* formation water) only (Fig. 6–1). Rice & Claypool (1981) argue that hydrostatically increasing methane solubilities at depth can serve as a holding mechanism until the sediments are compacted, and traps and seals are formed. Since rates of single- and multi-phase flow differ from those of diffusive transport by up to two orders of magnitude (England & MacKenzie 1989, England 1990) it is an important element of cap rock risk assessment to determine the degree of hydrocarbon saturation within the pore space. In fact, the saturation determines which of the above mentioned flow concepts is most suited for a given stratigraphic interval along the borehole.

Coupled Diffusion-Flow Concept Prinzhofer *et al.* (2000b & 2001) used a transient leakage model to estimate reservoir leakage by methane diffusion in conjunction with mobile gas formation within the overlying, stratified and water-wet cap rock. The methane partial pressure of intruded gas was examined for its potential of forming a methane gas phase from water-dissolved gas.

The potential for gas exsolution in a cap rock is almost zero when assuming only a single diffusivity contrast between a seal layer (low diffusivity; *e.g.* mudstone) and the overlying rocks (high diffusivity, *e.g.* massive sandstone; Brown 2001, Prinzhofer *et al.* 2001). However, the composition of a real mudstone cap rock is commonly stratified with interbedded thin sandstone layers or lenses. Prinzhofer *et al.*'s (2000b & 2001) model indicates a decrease of the methane flux within such a discontinuity, rapidly inducing a local accumulation beneath it, with methane gas concentrations potentially crossing the satu-

ration line (Fig. 6–3). The generated gas phase may subsequently cross the next horizon in solution. Finally, the recurrence of this flux variation results in the formation of several gas phases inside the seal section and above, *i.e.* the reservoir is eventually leaking in methane (Prinzhofer *et al.* 2001). However, the authors emphasize that the exsolution of a gas phase is more likely in the lower part of a laminated mudstone cap rock, thus methane leakage may not be categorical, most likely depending on the thickness of the seal section, the real thickness of each shale layer (millimetre to several metres) and the pressure of the hydrocarbon column in the reservoir.

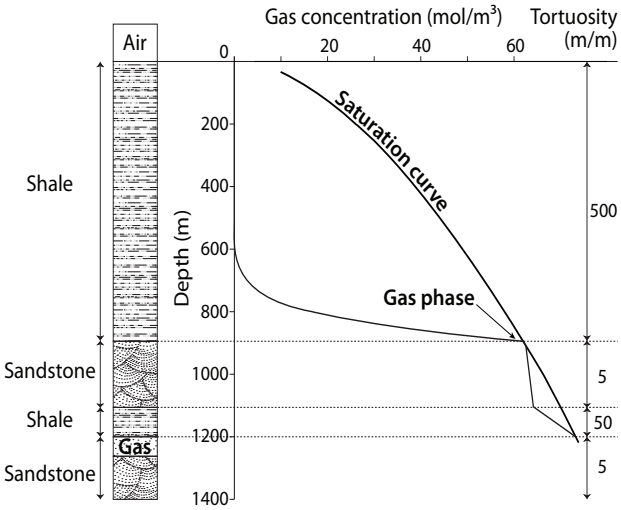

Figure 6–3 Curve of gas saturation in a sedimentary column that has a thermal gradient of 40°C/km and a gas profile for a diffusion time of 70 m.y. With this profile, consisting of four cells of mudstone and sandstone that have diffusivity contrasts of 5, 50, 5, and 500, respectively, a gas phase does appear after transport through water by dissolution/diffusion after 70 m.y. (from Prinzhofer *et al.* 2001).

Synopsis of Chapter 6 Undoubtedly, the ubiquitous presence of microbial gas described in Part I has severe consequences for vertical net leakage through mudstone pore space. An adaptation of Prinzhofer *et al.*'s (2000b & 2001) coupled diffusion-advection model on the facies scale to Whiticar's (2002) ideas on the pore scale severely shortens the net distance that individual gas molecules need to bridge between gas bubbles via diffusion. At the same time, however, a hypothetical omnipresence of gas saturated pore water within the methanogen window would severely reduce the (vertical) dissolved gas gradient and therefore reduces diffusion rates. Shorter net diffusion distance and slower diffusion rates would have the potential to neutralise each other, *i.e.* Prinzhofer *et al.*'s (2000b & 2001) model would not be applicable to cap rocks that host a strong viable microbial gas source – especially if internal gas pressure build-up is capable of microfracturing (which is not expected in this case study). In addition, interstitial water already saturated with microbial gas would have lost its buffer effect with respect to free thermogenic gas that is travelling within the structural water network, *i.e.* there is lower diffusive volume loss from advectively migrating gas phases.

This study is specifically focused on the gas saturation within mudstone intervals in order to test whether rapid leakage through the pore space is possible. A route map through the saturation modelling approach is found at the beginning of Chapter 7.

Chapter 7 The saturation model

Hydrocarbon saturation as defined in the previous chapter is a function of hydrocarbon concentration and its solubility in the surrounding formation water. There are a number of different procedures in chemical engineering and petroleum geochemistry that range from analytical to empirical evaluation of gas-in-liquid and liquid-in-gas solubility (see review in de Hemptinne *et al.* 1998a). While the published equations of state (EOS) are supported by scientific scrutiny of stable phase equilibria they require input data that are usually not available from conventional boreholes neither in quality nor quantity.

Instead, time and cost management has led to the development of a highly specialised petroleum engineering branch under the umbrella of petrophysics. Reservoir saturations can be deduced from calibration of empirical models that need to account for wireline log manufacturer, tool settings, and individual borehole conditions (Hearst *et al.* 2000). In addition, petrophysicists need to assess regional and stratigraphic environmental conditions related to basin burial history (incl. temperature gradients, pressure estimation/prediction, sediment provenance/mineralogy, cementation factors, etc.). An experienced petrophysicist will be able to calibrate reservoir saturation from a conventional log suite with sufficient accuracy although he/she usually has to do so without direct calibration data; 'sufficient accuracy' meaning sufficient to keep the estimate/recovery ratio of in place hydrocarbons close to unity.

Although there are multiple petrophysical indicators for the general presence of gas in the subsurface most of them are insensitive to low saturations but sufficient to detect gas pockets and reservoirs of conventional commercial interest (Eyvazzadeh *et al.* 2004). Physical properties such as low density and low conductivity of a free hydrocarbon phase as opposed to those of both rock matrix and brine cause characteristic acoustic wave velocities (in seismic imaging and sonic wireline signals) and exceptionally high resistivity log signals (Tiab & Donaldson 2004). For example, a free gas phase in the pore network of a rock reduces the compressional wave velocity (Vp) and increases shear wave velocity (*Vs*), *i.e.* the Vp/*Vs* ratio decreases with increasing gas content (*e.g.* Tiab & Donaldson 2004, Zinszner & Pellerin 2007). The effect of the saturating fluid on velocities can be calculated from Gassmann's (1951) equation that provides an explicit expression of the parameters in Biot's (1941) poromechanical theory which relates matrix and pore stresses (or pressures) to the litho-elastic properties (bulk moduli). However, the extent to which acoustic waves pick up low gas contents is controversial; although some authors claim that low gas saturations may be detected within reservoirs from velocity logs upon subtraction of the lithological parameters (Knight *et al.* 1998, Li 2004) current consensus

is that gas is not detectable below a threshold of roughly 5 vol.% (J. Cartwright personal communication). Apart from general uncertainties in parameter estimation (effective stress, bulk density, porosity; see Mondol *et al.* 2007) Vp/*Vs* is a particularly unreliable proxy for low saturations in the non-reservoir since it has been shown to additionally interfere with clay mineral properties (Lee 2003).

In terms of electric signals, salts dissolved in formation water provide an excellent conductive medium (brine ↔ electrolyte) opposed to non-polar and therefore insulating hydrocarbons. Electrical charge that is inflicted onto the formation by an external source literally follows the path of least resistance. In water-wet sandstones the electrical current discharges via the brine network while most of the interstitial hydrocarbon is bypassed resulting in a moderate bulk resistivity. Disconnection of the brine by free gas in a hydrocarbon-wet sandstone leads to a substantial resistivity increase since the electrical current is forced to partly bridge the isolated electrolyte via poorly conductive gas phase and mineral surfaces (Tiab & Donaldson 2004). Thus, hydrocarbon saturation can be estimated from resistivity logs if the conductive property of the rock matrix is known (Archie 1942). Although electrical log models that account for the surface conductivity of clay crystalites may certainly lead to realistic pore water salinity estimates (Revil *et al.* 1998 – and references therein) they will not pick up free gas signals in mudstones due to rapid discharge via the conductive clay framework while isolated gas bubbles in the pore space – that act as conductivity buffer in reservoir sands – are apparently bypassed and thereby invisible to the receiver of an electrical wireline tool (Zinszner & Pellerin 2007, K. Kurtev personal communication). Consequently, the hydrocarbon potential of complex interbedded mudstone-sandstone reservoirs is commonly underestimated from electrical logs by up to 30% (Worthington 2009).

This study is particularly focused on fine grained and clay-rich sediments so the classic models involving conventional wireline log signals will certainly not be suitable for resolving hydrocarbons in mudstone cap rock intervals. Instead, nuclear radiation logs are of particular interest to infer total gas (TG) concentrations because the associated signals are

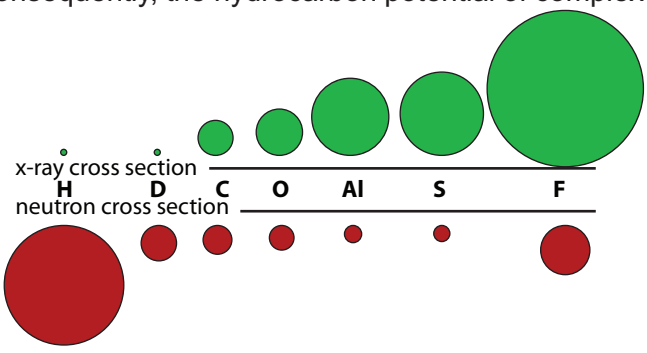

Figure 7–1 Signal strength of selected elements bombarded with X-rays and neutrons. X-rays as part of the electromagnetic wave spectrum interact with the electron shell and consequently the scattering cross section increases roughly as a function of atomic number and electronegativity. In contrast, neutrons are elementary particles without charge and are scattered by the atom's nucleus. Hydrogen is particularly sensitive to neutron bombardment because its nucleus consists of a single proton that has almost the same mass as the arriving neutrons (Neumann 2006). Subtraction of the neutron scatter signal obtained from the remaining elements within the bulk formation using the X-ray scatter signal yields a proxy for hydrogen content which will give an estimate of molar hydrocarbon concentration (from Neumann 2006).

largely indifferent to phase behaviour (solid matrix ↔ brine with dissolved gas ↔ free gas; Hearst *et al.* 2000; Fig. 7–1). Although nuclear log data has been used to infer empirical input parameters such as Archie's (1942) saturation exponent for saturation models from electrical logs (Hastings 1990), a direct correlation to hydrocarbon content poses a novel approach. In this study, the gas concentrations measured while drilling along with vast empirical grain and pore size information from the core section (as described in Chapter 5) are used for direct calibration of the nuclear and other relevant log signals. Concept and workflow for obtaining a suitable wireline TG model and other parameters necessary for the conversion into pore space saturations via equations of state (EOS) from chemical engineering are outlined in Figure 7–2.

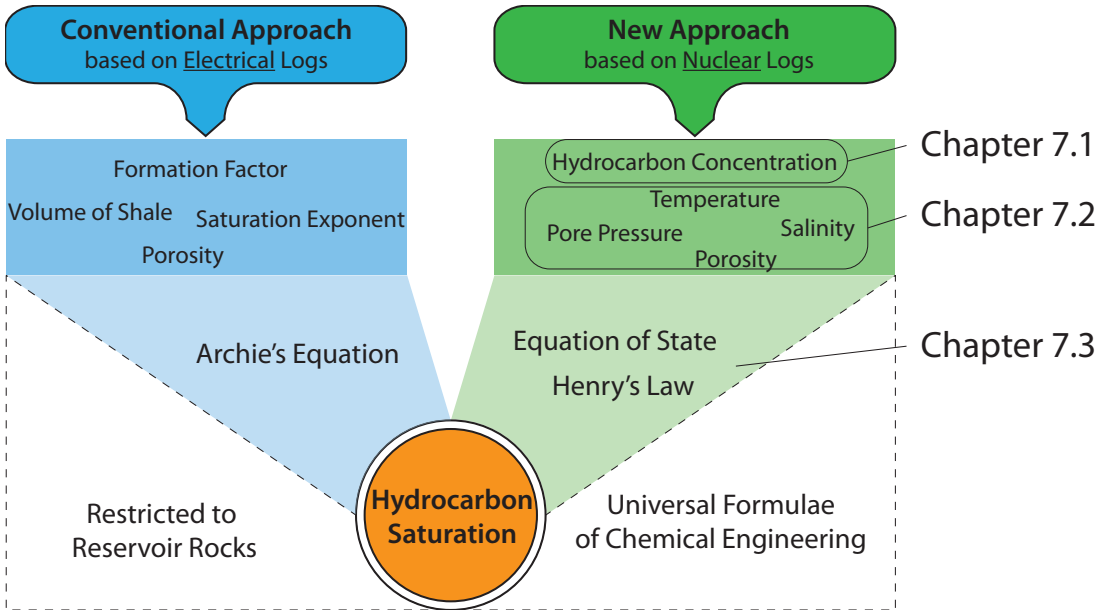

Figure 7–2 Workflow for hydrocarbon saturation model. A new approach is based on a proxy for phase-independent hydrocarbons from nuclear log signals (Chapter 7.1). Under *in situ* conditions (Chapter 7.2) the partition of the modelled gas concentrations in aqueous solution and free gas phase is calculated using standard solubility equations from chemical engineering (Chapter 7.3). In contrast to the conventional approach, all the input parameters are basic physical parameters for which calibration data is readily available. This is an important benefit since the standard equations used for the new saturation model are highly accurate and therefore compensate for the fact that direct calibration data of hydrocarbon saturation is commonly not available.

7.1 A novel approach for modelling gas concentrations

Modelling hydrocarbon saturation is a straight forward task if adequate concentration estimates are available. This section demonstrates how gas concentration measurements from borehole discharge can be used to calibrate nuclear wireline logs for molar hydrocarbon signals. The resulting total gas (TG) model will be processed under consideration of *in situ* environmental parameters (Chapter 7.2) to hydrocarbon saturation estimates in Chapter 7.3.

Normalisation of measured gas concentrations A universal presence of hydrocarbon gas in the formation fluid is indicated by the record of a total gas (TG) concentration across the non-reservoir from wellsite gas chromatographs (GC). These analytical devices are standard health & safety equipment that measure the hydrocarbon gas content of the borehole fluid discharge during drilling. Data collected by wellsite GCs are found among fluid properties, circulation rates and penetration rates as an essential part of the mudlog report (*e.g.* Fig. 7–4).

TG GC logs provide continuous information at a large scale (borehole dimensions) and relatively high resolution (~ 1m) about a volumetric parameter that defines the commercial outcome of a drilling project. In fact, it is the only directly measured gas concentration parameter that would allow the calibration of wireline log saturation models. However, the measured TG data is twisted and distorted by various concomitant phenomena of drilling and coring – in both dimensions: depth and magnitude (Whittaker 1985, T. Dodd personal communication).

Although normalisation of the equivalent total gas concentration (TGequiv in vol.%) over both incremental borehole circulation rates (Vflow in m³/min) and volume flow rate of drilled cuttings (Vcut in m³/min) rescales the raw TG log into relative proportion (Equ. 7a) the absolute magnitude of the thereby calculated TG GCnorm becomes distorted (Fig. 7–3).

TG GCnorm [%norm] = TG GCequiv / Vflow / Vcut ***(7a)***

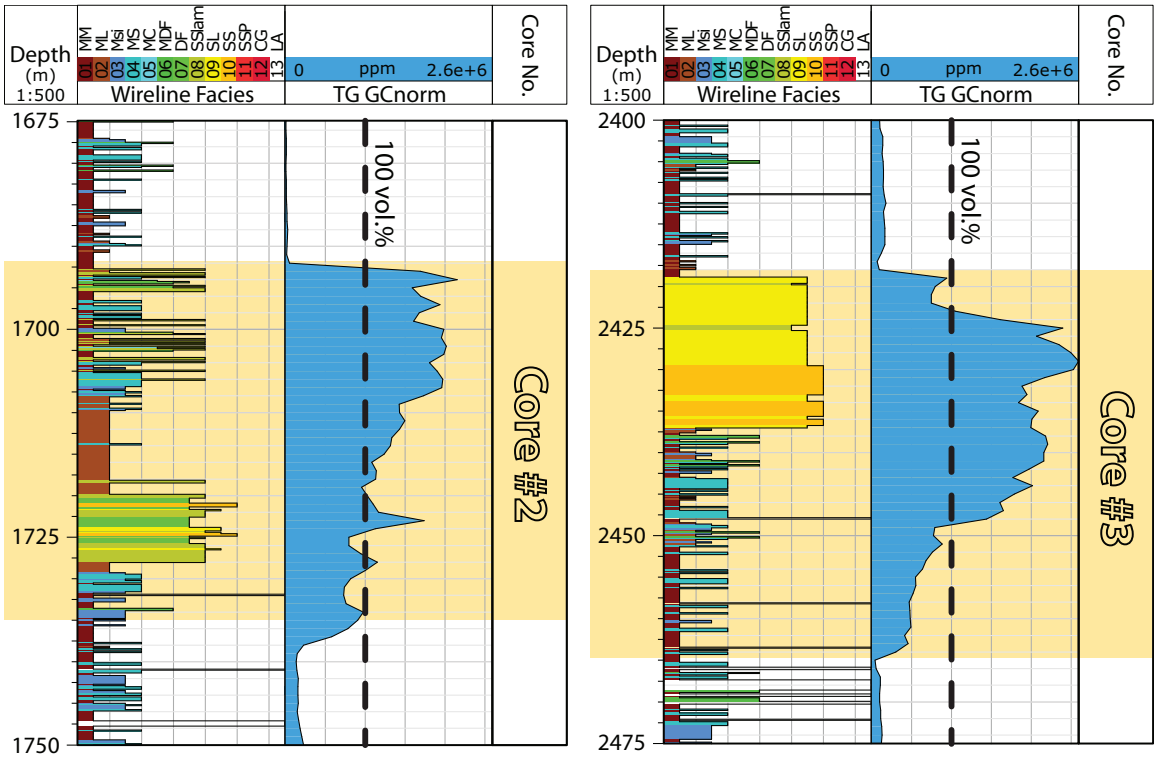

Figure 7–3 Normalisation artefacts may result in TG concentrations exceeding 100%. This is a particular coring phenomenon since measured TG is high, flow rates very low, and the cuttings volume usually overestimated due to core preservation. Examples from Well B22.

In other words, normalisation of measured hydrocarbon concentrations by Equation 7a is essential for elimination of differential circulation and penetration effects on the TG borehole profile but – at the same time – distorts the measurement scale across the 100 vol.% boundary as illustrated in Figure 7–3. Resetting the distorted scale into real concentrations that refer to a unit volume of rock is the essential aim of the calibration procedure that will follow.

First, since the GC measures in units of volume per cent per borehole discharge at the recorded pressure P (Pa) and temperature T (°K) within the measurement cell the TG record may be converted into moles per cubic metre via the Ideal Gas Law[1] (Equ. 7b) with the volumetric TG GCnorm in m³/m³ and gas constant R in Pa*m³/K/mol.

$$\text{TG GCnorm [mol/m}^3\text{ norm]} = P \cdot \text{TG GCnorm} / (R \cdot T) \qquad \textit{(7b)}$$

These units are more practical for wireline log integration because the PT conditions in the measurement cell do not reflect those of the gas's native environment (Fig. 7–4).

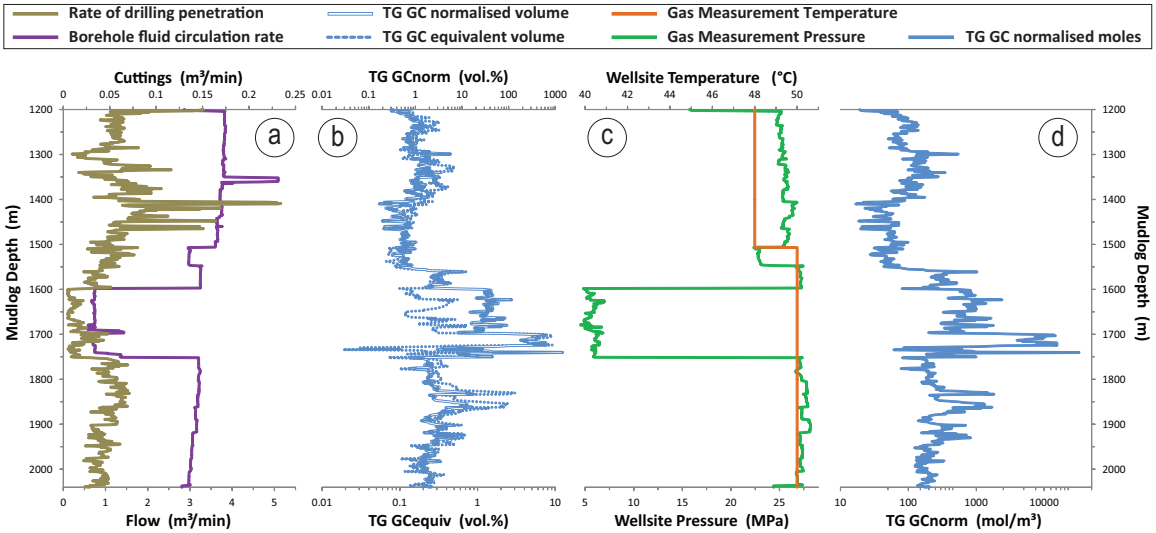

Figure 7–4 (a,b) Normalisation of TG GCequiv and (c,d) subsequent conversion from volumetric into molar units. The entire parameter record (incl. temperature and pressure) refers to the borehole discharge during drilling. Example from Well B19.

Rationale for calibrating distorted concentration logs The aforementioned distortion of the mudlog record poses a major dilemma because – when aiming for a reproduction of TG logs that are devoid of both normalisation artefacts and relative depth uncertainties – a direct integration ("cross-plot") of mudlogged TG with wireline log signals is impossible. Alternatively, this study exploits the opportunities of indirect integration by the careful determination of a wireline log model across a borehole section that (1) has a rela-

1 The use of mudlogged pore pressures P in Equation 7b yields a rough approximation since the effective partial pressure or fugacity of the gas phase is not yet considered. Still, this procedure is considered valid at this stage of the TG model because (1) the pressure and temperature within the GC cell are quite constant while drilling through the non-reservoir (*e.g.* Fig. 7–4d), and (2) the distorted absolute TG GC volumes will need to be reset into realistic values anyway. Fugacities and thus 'real gas' behaviour in terms of hydrocarbon volumes will be subject to the final saturation model in Chapter 7.3.

tively steady fluid circulation and drilling penetration history in order to keep normalisation artefacts as low as possible and (2) has a relatively wide range of TG GCnorm outside the cored reservoir interval in order to cover the largest possible fraction of the “true” TG range (ideally 0 to 100% pore space).

The benefits of a quality TG GCnorm reproduction from wireline log signals are enormous: (1) a wireline TG model may serve as reference for mudlog depth synchronisation which would effectively shift the gas geochemical and isotope data into the position of their native wireline facies, (2) modelled peak TG concentration inside the reservoir may be rescaled to the associated porosity (assuming a gas saturation close to 100% pore space) and thereby (re-)assign a quantitative sense to the TG log, and finally (3) serve as input parameter to a conventional saturation model as a function of gas solubility in the pore brine. A simplified forward model under controlled conditions will briefly illustrate the concept of mudlog-to-wireline log integration in the following paragraphs.

Let us assume we obtain an artificial log that covers a 1000m depth interval and incorporates random values between 5 and 75 units (Signal A in Fig. 7–5). Signal A is an unspecified property that is linked to another signal B by a simple exponential function. Surely, in this example the precise function is known to the author, and anyone who wants to specify the relation between Signal A and B would suffice with a simple cross-plot (Fig. 7–6a). However, such strategy would fail if a simple artificial shift was applied to the measurement depth of Signal B (Figs. 7–5b and 7–6b). This artificial situation is a simplified version of the dilemma that is associated with the mudlog-to-wireline log integration. Here, Signal A would be any wireline log model that may have a more or less direct physical relation to the TG measured while drilling (→ Signal B), but the precise relationship between both cannot be deduced via a direct cross-plot due to severe depth mismatches.

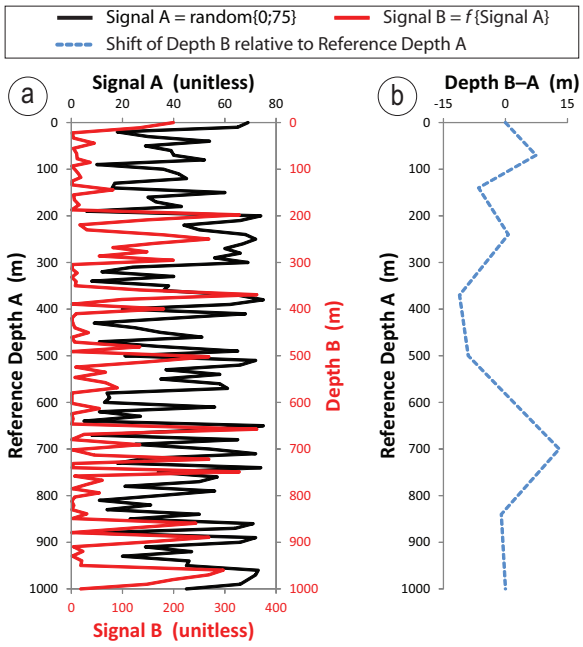

Figure 7–5 (a) Although Signal B is genetically a function of Signal A the relation between both parameters cannot be directly deduced because (b) the measurement depth of B is not synchronised.

It follows that a recovery of both conversion function and measurement depth would require cross-plotting Signal A and B after they have been stripped of their incompatible depth record, reducing them to a single dimension: the magnitude. This goal is achieved

by plotting the array distributions (or percentiles) and the linking function Signal B = *f*{Signal A} becomes visible to anyone who did not set up this little example (Fig. 7–6c). Further, it will be easy to comprehend that once the conversion function is known the depth shift of Signal B (or TG GCnorm) to Signal A (or wireline log proxy) can be fixed by peak-matching.

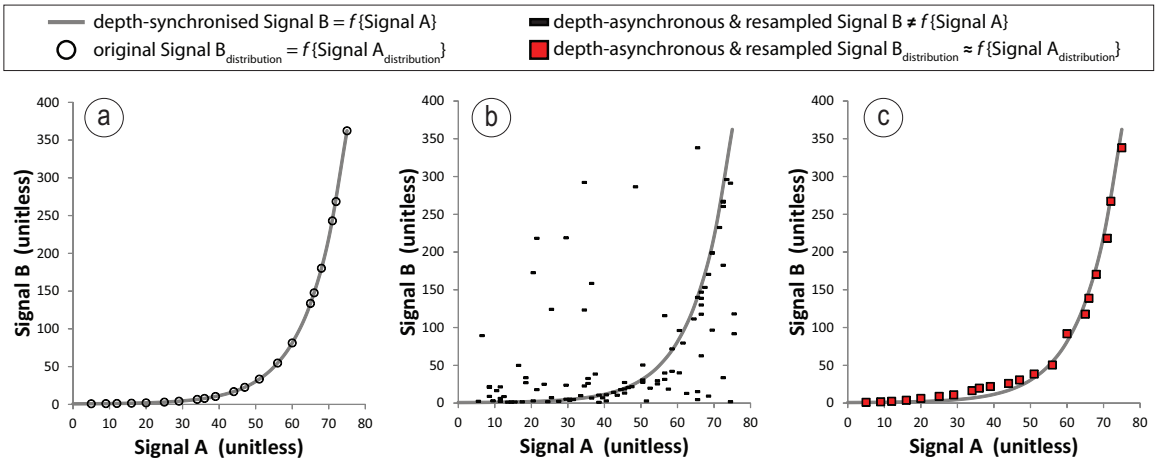

Figure 7–6 (a) Genetic relationship between Signal A and B is (b) not trackable upon distortion of Signal B's measurement depth. (c) A distribution cross-plot is a promising indirect method to integrate two different signals with an unknown depth mismatch.

Molar gas concentrations from nuclear log signals Clearly, before application of the integration procedure described above it is necessary to determine a wireline log signal or signal combination that qualifies as a reference for the mudlog TG GCnorm. In contrast to traditional wireline saturation models a signal is required that is sensitive to both a free gas phase and gas dissolved in aqueous solution (see Fig. 6–1). Such conditions are met by downhole measurements of gamma and neutron radiation. They provide useful information about the element assemblage of minerals and pore fluid alike (Chapter 6).

For example, as the formation is radiated with gamma rays from a radioactive source they collide with electrons in the rock matrix and pore fluid. Back-scattered gamma rays that reach the detector are a function of electron density in the formation and consequently bulk density. Hydrocarbons are indicated by abnormally high density log porosities (Hearst *et al.* 2000). Likewise, emitted neutrons are preferentially captured by hydrogen nuclei that have principally the same mass as the neutron. Detection of this energy loss via decreasing neutron counts in the vicinity of the logging tool can be translated into water content as a fraction of the bulk formation volume (Hearst *et al.* 2000). Such neutron porosity logs are commonly referenced to calcite as a default mineral, *i.e.* the measured porosity values will be true in limestone zones (Doveton 1999). However, the raw neutron porosity value is generally an overestimate because hydrogen bound in clays or hydrocarbons also contributes to the detected neutron capture (Hearst *et al.* 2000, USDI 2001).

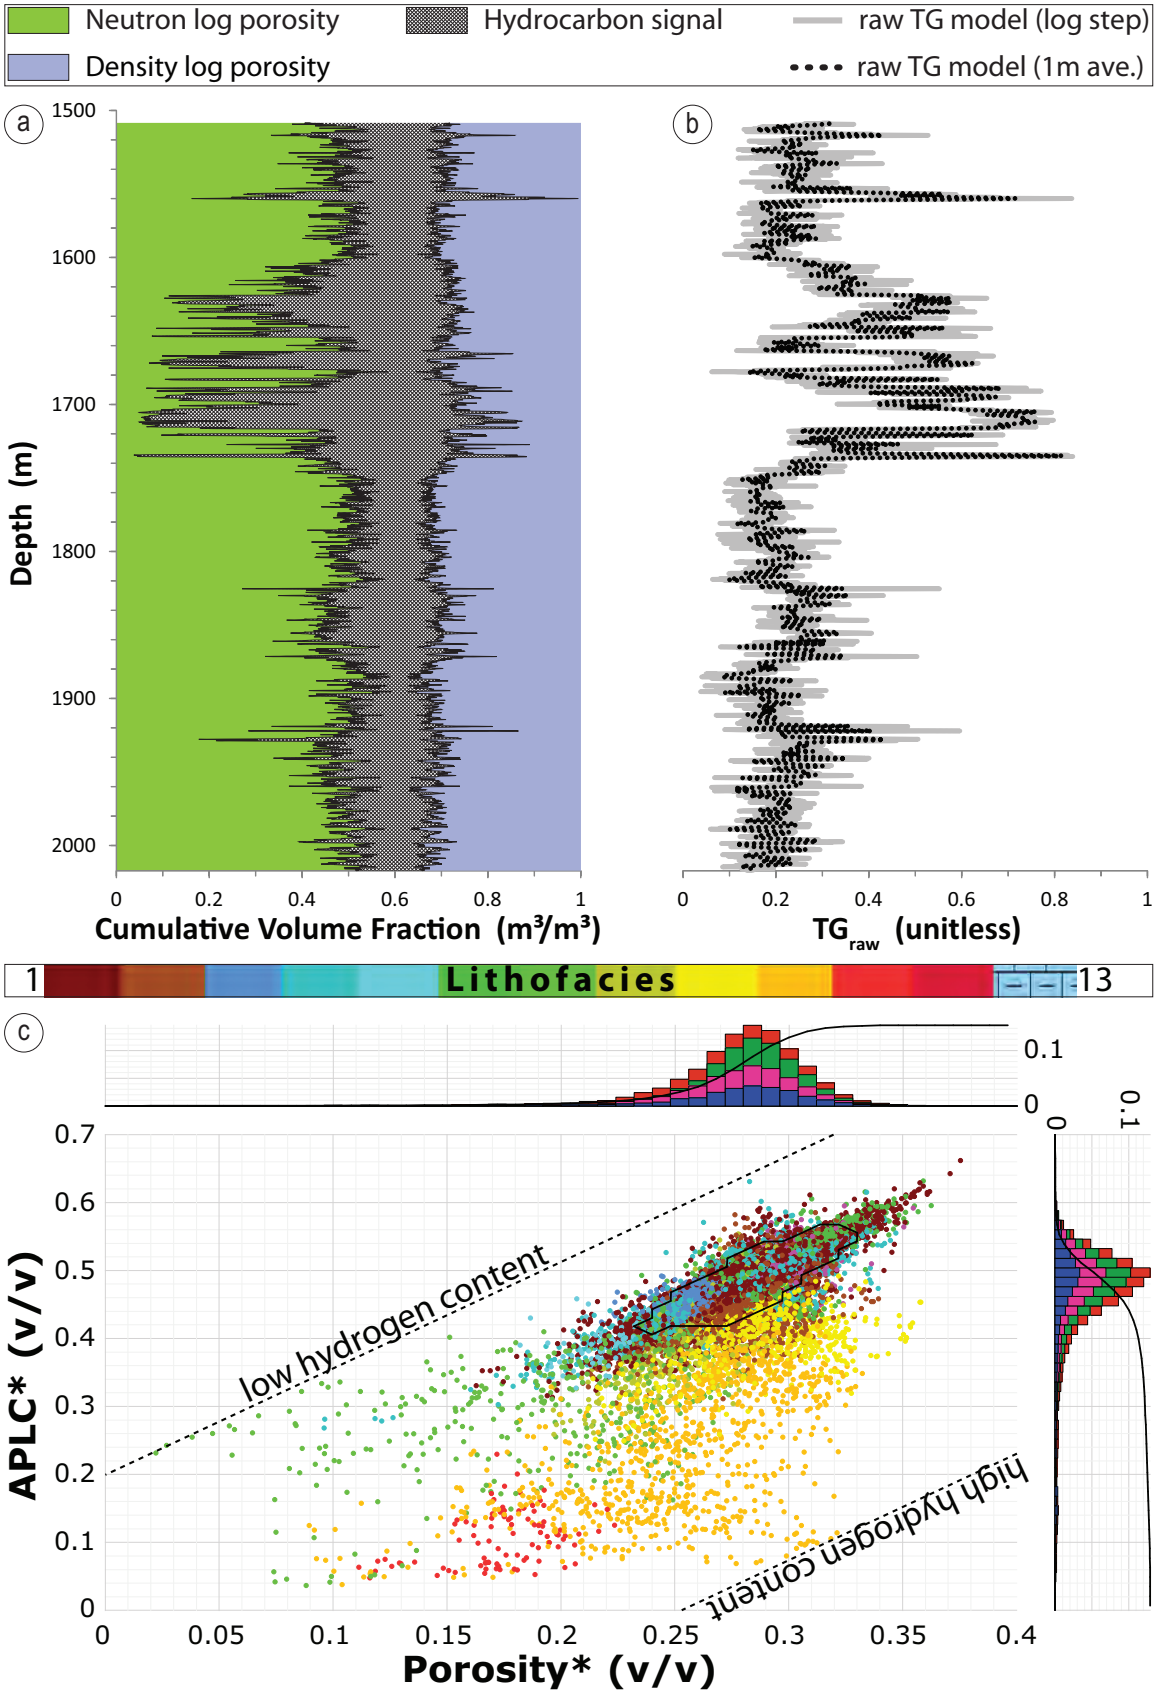

Figure 7–7 (a,b) The difference between density log porosity and neutron porosity appears to vary with hydrogen content (see text) and resembles the TG GCnorm mudlog record. (c) The link between the proposed TG model and hydrocarbon content is supported by a strong deviation for presumably gas-saturated reservoir sandstones in the crossplot between depth-detrended neutron porosity (APLC*) and density log porosity (Porosity*) of the four wells under investigation (logs are harmonised with respect to Well B19; see Chapter 5 for details). Frequencies of the four investigated wells are colour-coded according to Figure 7–9. (d) The causality of the TG model is not fully constrained since both incorporated log signals respond to a similar definition of pore space, but it is suspected that the missing link is based on the preferential adsorption of neutrons by hydrogen atoms opposed to element-indifferent perception of the (electron) density wireline tool (adopted from Zinszner & Pellerin 2007).

It was noted that neutron porosity logs from the available wells have a much higher amplitude than the density log porosity: neutron log porosity exceeds density log porosity in the non-reservoir whereas it is lower in the gas-bearing reservoir section (Figs. 7–7a,b). The quasi-linear trend for the mudstones facies implies that mudstone porosities are measured from both methods to comparably reliable extent although with a shift in magnitude (Fig. 7–7c). The strongly linear behaviour of mudstones in Figure 7–7c suggests that the model sensitivity with respect to clay-bound hydrogen is low and uniform and can be accounted for during post-processing. The causality of the proposed TG model is presumably due to the preferential neutron capture by hydrogen atoms (Fig. 7–1) that causes stronger signal fluctuations compared to the density log (Fig. 7–8). On an elemental basis, the TG model is based on the difference between neutron and electron count and will foster a simple empirical model that reflects the amount of hydrogen per unit volume of rock as a proxy for TG concentrations (see Fig. 7–1). The following paragraphs will guide through the model calibration which will eventually resolve in a modelled TG log that has striking resemblance with the (highest quality) section of the TG GCnorm.

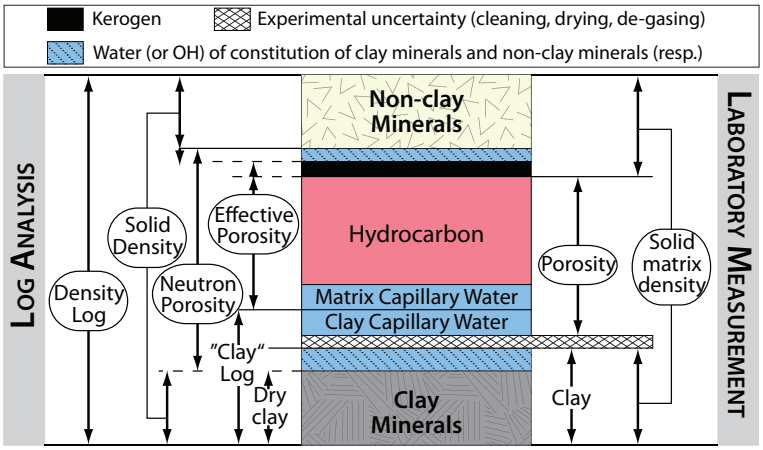

Figure 7–8 Scheme showing different porosity classifications. The causality of the TG model is not fully constrained since both incorporated log signals respond to a similar definition of pore space, but it is suspected that the missing link is based on the preferential adsorption of neutrons by hydrogen atoms opposed to element-indifferent perception of the (electron) density wireline tool (see also Fig. 7–1; adopted from Zinszner & Pellerin 2007).

The mudlog-to-wireline log integration and subsequent calibration has been performed for the sub-reservoir section of Well B19. This interval was chosen because the flow and penetration conditions during drilling have been relatively stable and the actual TG variance presumably quite high (see Figs. 7–4 and 7–7b below ~1760m). The wireline TG model was resampled to average values for every full metre in order to meet the mudlog resolution (Fig. 7–7b) before the distributions of both logs were cross-plotted to account for the depth issue as demonstrated earlier in this chapter (Figs. 7–5 and 7–6). This procedure yields an uncalibrated function for the conversion of the wireline TG proxy into TG GCnorm similar to the curve in Figure 7–9b. The curve shape suggests a quasi-linear relation between the TG model and measured TG GCnorm values in this section. Hence, the preliminary output values of this uncalibrated TG model (not shown) are assumed to be true for very high gas concentrations (*e.g.* in reservoir sands) if only the absolute

values can be scaled to the true magnitude. This problem was overcome by assigning 100% gas saturation to the highest TG model value, *i.e.* the uncalibrated molar values were temporarily converted into uncalibrated volumes using the pressure corrected Ideal Gas Law (Equ. 7l) and the *in situ* PT conditions that are described in Chapter 7.2.

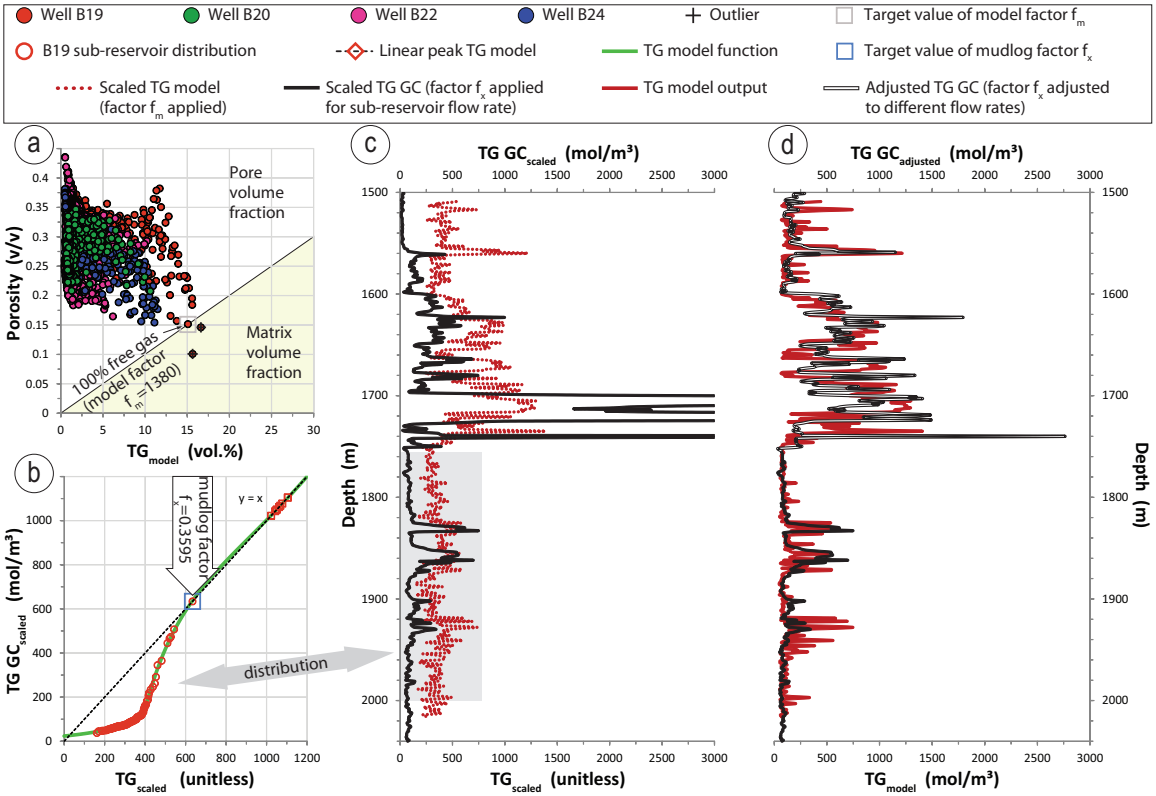

Figure 7–9 (a) Model calibration factor f_m establishes a causal link between maximum gas volume and the available pore space by assigning 100% hydrocarbon saturation to the peak TG value. Two outliers are neither in the reservoir section nor spatially related to the remaining data points in this plot. (b) Mudlog scale factor f_x for the B19 sub-reservoir fits the highest TG value from this interval onto the proposed linear 1:1 relation for peak-modelled values within the B19 reservoir section. (c) Modelled TG values prior to and (d) after application of the distribution conversion function (Equ. 7e).

The raw volumetric model was then propagated for all wells (harmonised with respect to Well B19) and the peak reservoir TG volume scaled to the associated "true" porosity as described in the next chapter (Fig. 7–9a). The hereby resulting factor f_m=1380 scales the raw model values in Figure 7–7b to the magnitude in Figures 7–9b and 7–9c. The data gap between the supposed linear reservoir gas trend and the maximum value within the model calibration interval of the B19 sub-reservoir was closed by assuming that the latter is at the verge of linearity (see curve shape in Fig. 7–9b). Consequently, the mudlog calibration target in Figure 7–9b was met by applying a factor f_x to the mudlogged TG GCnorm (*e.g.* f_x=0.3595 for the calibration interval). This factor is not of generic nature but empirically corrects for normalisation artefacts from unstable drilling conditions (circulation, penetration) and sensitivity of the different wellsite GC.

The described procedure enables a regression of the data points in Figure 7–9b as represented by the green curve therein. The full conversion formula from raw TG model

(unitless; Fig. 7–7b) via scaled TG model (unitless scaled, Fig. 7–9c) to calibrated TG model (mol/m³; Fig. 7–9d) is as follows:

$$TG_{raw}\ [unitless] = 1 - PHI_{detrend} - APLC_{detrend} \quad \textit{(7c)}$$

$$TG_{scaled}\ [unitless\ scaled] = TG_{raw} \cdot f_m = TG_{raw} \cdot 1380 \quad \textit{(7d)}$$

$$TG_{model}\ [mol/m^3] = if\{\ TG_{scaled} < 420.6,\ 23.48 \cdot e^{(0.003805 \cdot TGscaled)} + 4.209 \cdot 10^{-5} \cdot e^{(0.03486 \cdot TGscaled)},$$

$$426.7 \cdot e^{(0.0008639 \cdot TGscaled)} - 6006 \cdot e^{(-0.006446 \cdot TGscaled)}\ \} \quad \textit{(7e)}$$

Since the full TG GCnorm log incorporates baseline shifts due to differential flow and drilling conditions (Fig. 7–4a) the mudlog factor f_x can be adjusted to the calibration interval (*e.g.* Fig. 7–9d above 1760m; see Appendix A for remaining wells). These adjustments are not mandatory since they do not affect the TG model but recommended if a mudlog shift is intended. The distributions of thereby base-shifted TG GCnorm intervals of wells B20, B22, and B24 are plotted *versus* the uniform TG model as acquired from Well B19 in Figure 7–10. The fact that the calibrated TG function could be approximated for non-cored intervals of the remaining wells although the model was first established from the B19 sub-reservoir supports the validity of the approach and the rescaling procedure with all the assumptions stated. For the striking resemblance between modelled and measured values is referred to the figures in Appendix A which deals with the mudlog shifting procedure.

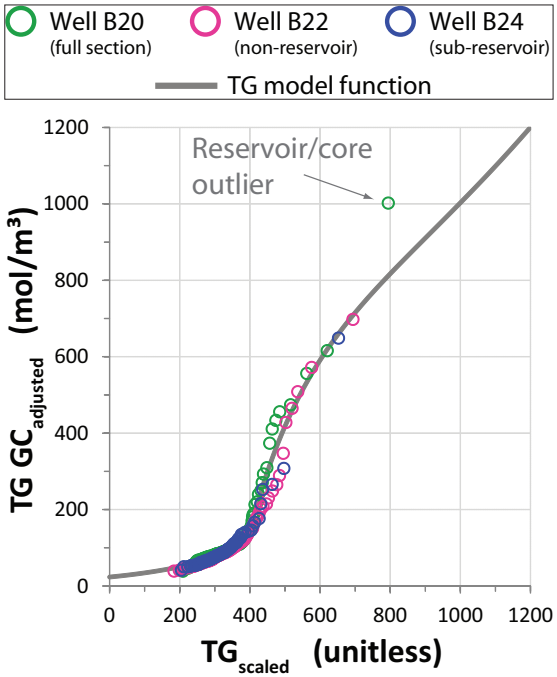

Figure 7–10 Adjusted distribution of TG GCnorm from the remaining wells as a preparatory step for mudlog shifting (Appendix A).

7.2 Acquisition of environmental parameters

The calibration procedure in Chapter 7.1 led to total gas (TG) concentrations that refer to the amount of hydrocarbon molecules (in moles) per unit volume of rock (m³). Basically, the calibrated TG concentrations need to be partitioned between dissolved and free gas to yield gas saturations. Conversion into hydrocarbon saturation requires a sufficiently accurate calibration of the available pore volume while pore pressure, formation temperature and pore water salinity are necessary to calculate the volume of the free gas phase under consideration of dissolution loss to the aqueous phase. Individual determination of these environmental parameters is the subject of the following sub-sections.

Porosity The pore volume of a natural sedimentary rock is a relative physical parameter especially if clay minerals are involved (Pearson 1999; see also Fig. 7–11). The net-negative charge of clay mineral surfaces leads to adhesion of dissolved cations and polar molecules that are enveloped by a layer of ordered water molecules (*e.g.* Waxman & Smits 1968). This so-called electric double layer along with dead-end and isolated pores slightly reduces the volume effective for fluid flow (Mitchell & Soga 2005). In addition, structural and inter-layer water and hydroxyl groups do not contribute to the flow network and are commonly subtracted from total porosity for the study of advective fluid transport through the pore network (Zinszner & Pellerin 2007). Between 0 and 75% of a total mudstone porosity can be inaccessible for advective fluid transport depending on the thickness of the diffuse double-layer as a function of clay surface charge and pore water salinity (Sevee 2010 – and references therein).

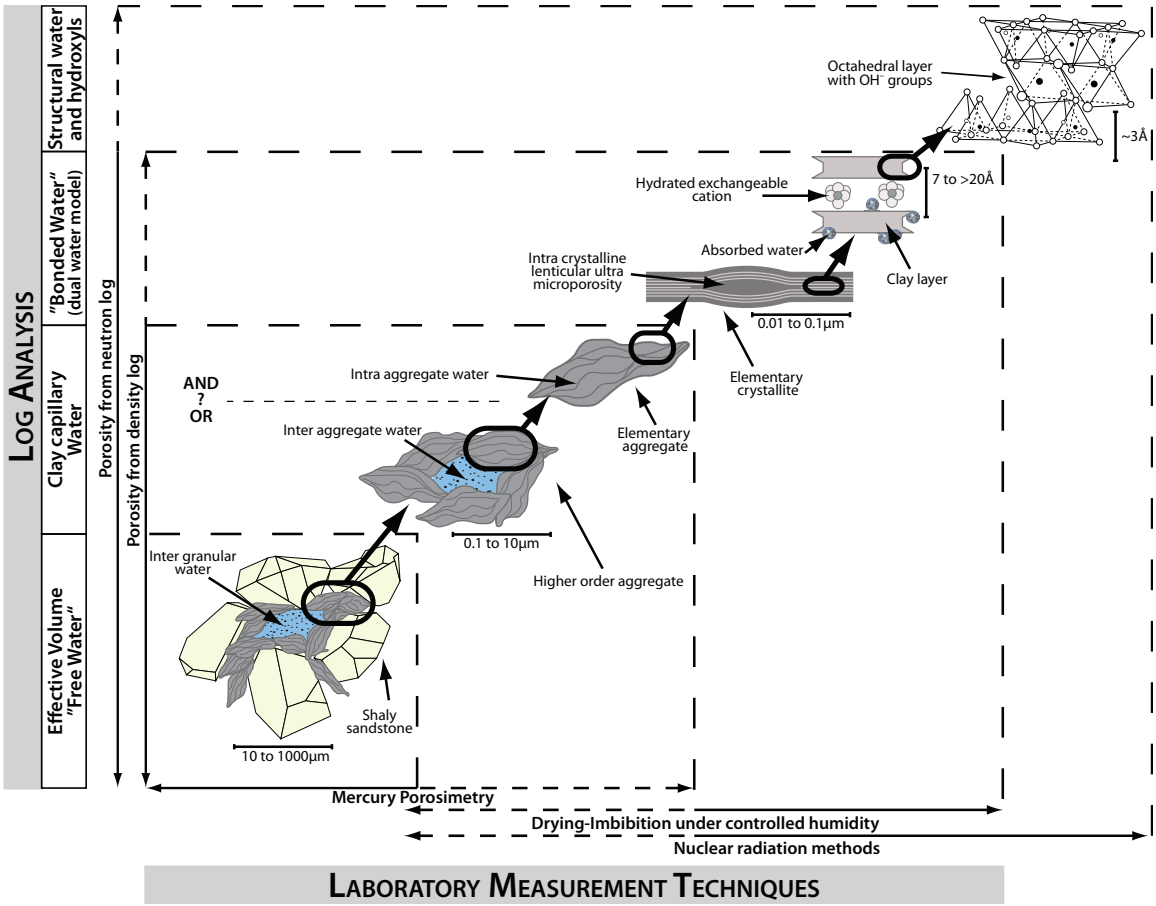

Figure 7–11 Porosity from humidity dried core samples is not directly comparable to porosity from density log because the former incorporates constitutional water of minerals and volume occupied by organic matter, *e.g.* the higher the clay content and the more organic the mudrock the higher is the overestimation of porosity from bulk density with respect to laboratory measured porosity (Figure adopted from Zinszner & Pellerin 2007, and modified after Woodhouse & Warner 2005).

In this work, however, the focus of interest is on the pore volume that is capable of hosting a mixture of water, dissolved salts, and hydrocarbon gas in order to calculate the overall gas saturation according to its solubility in a brine-filled pore space. Since both available porosity logs (from density and from neutron log) respond to clay-structural

water and hydroxyl molecules – which clearly do not participate to the pore space of interest (Woodhouse & Warner 2005) – it is recommended to test and calibrate the most suitable porosity log with humidity-dried and therefore representative total porosity from the conducted MIP experiments (Chapter 4.2).

The porosity from density log was the preferred calibration target since it is more likely to resemble the laboratory results rather than the neutron log (Fig. 7–11). Modelled core image (CI) porosities of massive mudstones (facies 1; see Chapter 5) were chosen as a calibration reference data set for three reasons: (1) the high clay content of facies 1 largely covers the grain size range of the core samples and upscaled values are thus realistic, (2) although the presence of clay-bound water in mudstones certainly leads to deviations between density logged porosity and mercury injection porosity a consistently large hydrocarbon component (that would lead to even higher deviations; Hearst *et al.* 2000) is unlikely and therefore disqualifies as a potential error source in contrast to most sandstone intervals, and (3) sandy sections have a generally lower total porosity than clay-rich sediments and are thus hardly affected by a clay-related calibration function that

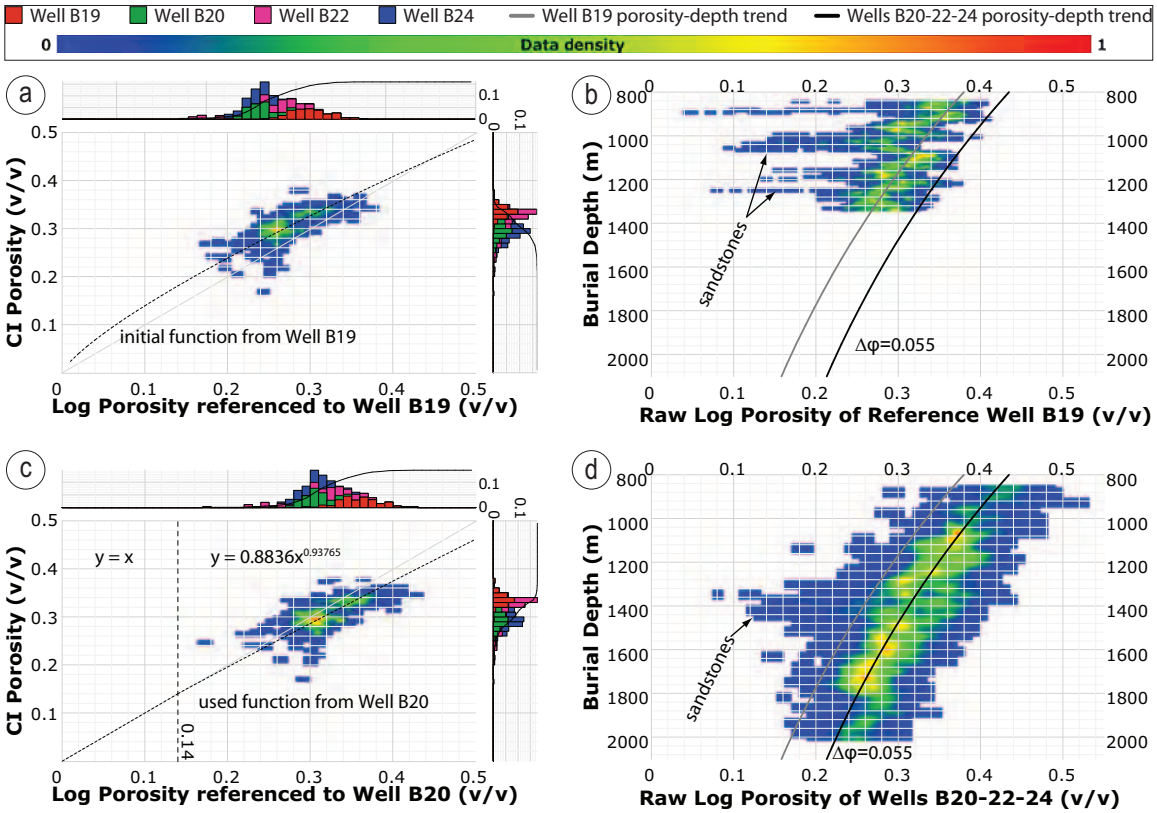

Figure 7–12 (a) A general overestimation of massive mudstone CI porosities with respect to density log porosities that were referenced to Well B19 contradicts from Figures 7–8 and 7–11 expected relations between these two parameters. This reversed offset of the upscaled mercury injection porosities from the 1:1 correlation line was found to be inherited from (b) a baseline-anomaly in the raw density log porosity trend of B19. The displayed B19 log signal offset of $\Delta\varphi$=0.055 m³/m³ is considered as an anomaly in the sensitivity settings of the log tool since the raw density log porosity trends from all the other wells (B20, B22, B24) show significantly higher porosities. (c-d) Re-referencing of the log signals to well B20 solved the problem insofar as the porosity parameter relationship is now close to unity and a slight calibration function can be applied on the precept that laboratory measurements yield slightly lower mudstone porosities when compared to density log porosities (see Figures 7–8 and 7–11).

is anticipated to deviate from a 1:1 ratio, particularly for high clay and porosity values (see Figures 7–8 and 7–11).

Figure 7–12a shows an initial calibration function for the porosity from density log (see Chapter 5.3 for pre-processing of log signals). The reason why the CI porosity is higher than the non-calibrated log porosity (although it should be the other way around, see above) was allocated to a characteristic baseline-shift in the density log of reference well B19 (Fig. 7–12b). A re-referencing with respect to the B20 density log solved the problem by revealing a common clay-to-log porosity trend close to unity (Figs. 7–12c,d). These findings underpin the importance of wireline log harmonisation between different wells and subsequent recalibration with physically measured data. The calibrated output porosity is shown in Figures 7–26 to 7–29.

Pressure It is widely acknowledged that the low permeabilities of mudrocks cause elevated pore pressures during shallow burial (< 70-100°C) if the rate of porosity loss from mechanical compaction and lateral forces is higher than the drainage rate of the pore fluids (Bjørlykke 1999, Swarbrick *et al.* 2002). Unlike in permeable reservoir and carrier rocks, restricted fluid conductivity of a mudstone layer prohibits real-time pressure equilibration with a penetrating borehole (Whittaker 1985, Dusenbery & Osoba 1986). It is therefore very difficult to directly measure the internal pore pressure of mudstone stratigraphy (Yang & Aplin 2004). High-quality pore pressure measurements from Schlumberger's MDT (Modular Dynamics Formation Tester) and other RFT (Repeat Formation Tester) tools have consequently been taken in widely permeable or thin-bedded stratigraphy only (*e.g.* Lyons & Plisga 2005). Such pressure data are available for wells B19, B20, and B24 and will serve as a calibration reference for the pressure model presented in the following paragraphs.

When assuming that the pore space provides the predominant drainage pathway and burial has been roughly linear and constant within the Nile Delta Pliocene (Fig. 1–2) the formation pressure of permeable sandstones can be roughly approximated as a function of burial depth. This assumption is apparently valid for non-reservoir sandstones as demonstrated in Figure 7–13. While the reservoirs are in pressure equilibrium and linear regressions with burial depth need no further amendment the global non-reservoir trend serves as a starting point for the calibration of a pore pressure model as a function of clay content for each individual well.

Yang & Aplin (2004) have bypassed the problem of missing mudstone pore pressure data by relating lithology (clay content) to compaction coefficients which – based on Terzaghi's (1943) relation in soil mechanics – yield an estimate of effective stress as a

function of porosity, with pore pressure resulting from the difference between total and effective stress. It follows that Yang & Aplin's (2004) procedure for pore pressure prediction requires the following input parameters: clay content, void ratio or porosity, and total or overburden stress. Calibrated porosity logs are available from the previous section and total stress is given by BP's overburden gradient (Equ. 5h, Chapter 5.1) plus the individual seawater column height at the drill sites. Clay content reflects the volume of grains smaller than 2µm and has, in contrast to clay mineral content no direct physical relation to any of the acquired wireline log signals. It was therefore decided to run TechLog's Ipsom ANN directly with the clay content from the CIGS model (see Chapter 5) that was resampled from its initial 5mm resolution to the log step. The applied ANN approach has strong parallels with the concept presented in Yang *et al.* (2002).

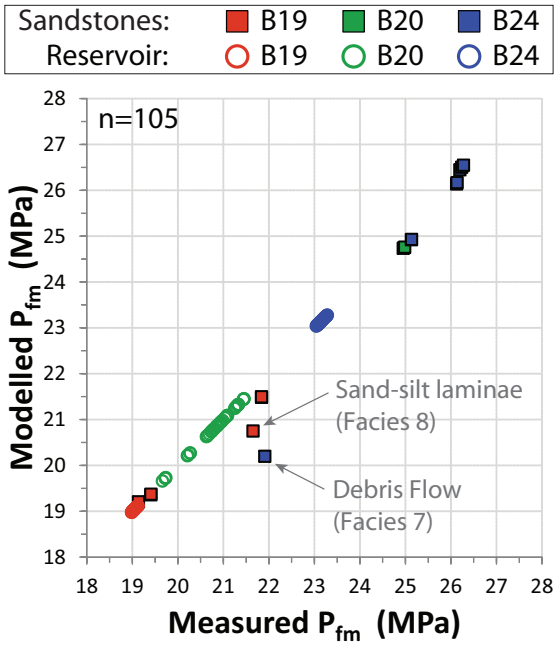

Figure 7–13 Formation pressure regressions both for reservoir and sand-rich non-reservoir intervals (facies 7-12). The reservoir pressure regressions are in the form of $P_{fmS} = a*z_{well}+b+P_{sea}$, where z_{well} is the burial depth (m) and P_{sea} the water pressure (MPa) at sea bottom. B19 reservoir: a = 0.001343, b = 11.22; B20 reservoir: a = 0.009857, b = 3.779; B24 reservoir: a = 0.001593, b = 14.72; global non-reservoir: $P_{fmS} = 0.010972*z_{well}+0.753*P_{sea}+2.771$.

Since ANN's require a manageable number of input categories to be trained on – like lithofacies in Part II – the entire CIGS clay content range from 0% to 100% has been split into 20 bins spanning 5% each. Ipsom was trained on all 4 wells simultaneously with the same model configuration as for the wireline facies propagation (Part II) with the sole exception of an increased number of Kohonen nodes (18^2) owing to the almost doubled amount of reference categories (Fig. 7–14). Since the CIGS model could not be calibrated for sand-rich sections facies 7 and ≥9 (see Fig. 5–3) were by default allocated with 0% clay and accordingly not processed with Yang & Aplin's (2004) pressure model.

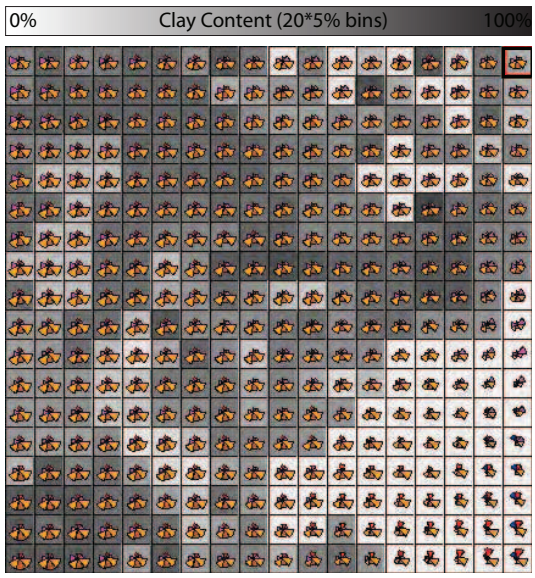

Figure 7–14 Ipsom's Kohonen map for the clay model shows a good spatial separation of recognised clay content for mud-rich facies (grey gradients). Sandy/neglected facies are represented by the white fields.

The uncalibrated ANN model output (not shown) yields high frequency pressure logs

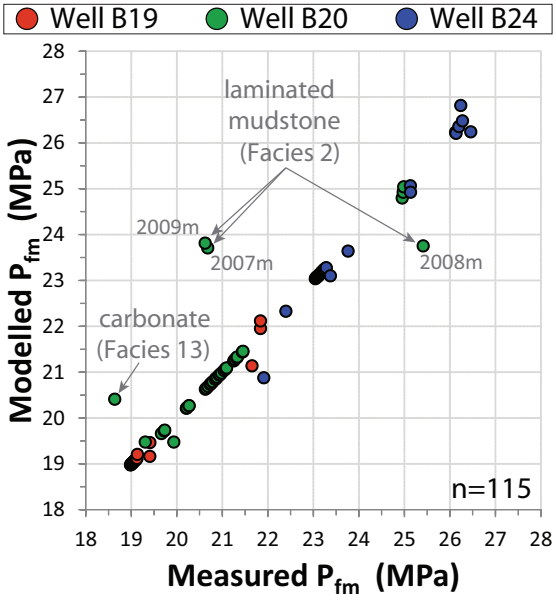

Figure 7–15 Calibrated formation pressure model reproduces the measured MDT pressure largely independent of facies type. Carbonate pore pressures (1 data point) possibly remain unconstrained although they could be strongly affected by the surrounding mudstone pressures. Three MDT measurements that were taken at 2007-2009m in B20 are biased since a gradient of >5 MPa per metre seems unlikely (the modelled value lies in between which is a fair compromise).

for clay-bearing facies (facies 1 to 6 and 8). In order to produce continuous pressure logs that match the sporadically measured data (MDT measurements, see Chapter 3.1) in the non-reservoir a fitting procedure has been applied by adjusting both the frequency of the clay-derived pressure log and – for each individual well – the slope of the global sandstone pressure gradient (applied to facies 7 and ≥9). Calibration quality is displayed in Figure 7–15.

Unfortunately, there are no MDT pressure data available for Well B22. In this case the mudlog pressure that is roughly valid for permeable units was utilised as calibration reference for the global non-reservoir pressure regression (see caption of Fig. 7–13). As for the B22 reservoirs, the average pressure gradient of wells B19 and B24 was taken as an estimate for two reasons: (1) B19 and B24 have a very similar reservoir pressure gradient though at different burial depth and (2) B20 with a much steeper gradient bears no commercial column height unlike B22. Further, as the vertical extent of B22's reservoir sections is known from the wireline facies output (Fig. 5–40) the magnitude of reservoir pressures was adjusted to intercept the non-reservoir pressure curve at reservoir top and base respectively.

Calibrated output pore pressure curves for all of the four wells are shown in Figures 7–26 to 7–29.

Temperature Formation temperature was measured via probing wireline tools (MDT, RFT) and non-probing tools (temperature log). Borehole fluid circulation can have a significant impact on the temperature of the adjacent formation fluids, *i.e.* quality of the measured data reduces with the length of period between drilling and logging (Lyons & Plisga 2005). Still, linear regressions of the measured data yield very good correlation coefficients (Figure 7–16) on assumption of a common sea bottom temperature of 13.7°C (Mastalerz *et al.* 2007).

Although the range of geothermal gradients is large it has been found to vary with geographic location of the drillsites. Therefore a geographical triangulation between the three

data-bearing wells (B5/B9/B24, see Fig. 1–3) closest to B22 was used to approximate its geothermal gradient under consideration of drillsite water depth.

Approximation of the formation temperature by linear gradients will suffice for the purpose of estimating hydrocarbon solubility in water since (1) temperature changes at a given pressure has a negligible impact on hydrocarbon solubility (*e.g.* de Hemptinne *et al.* 1998a, Pedersen & Christensen 2007) and (2) tectonically or hydrodynamically induced temperature inversions at depth have not been reported from this area.

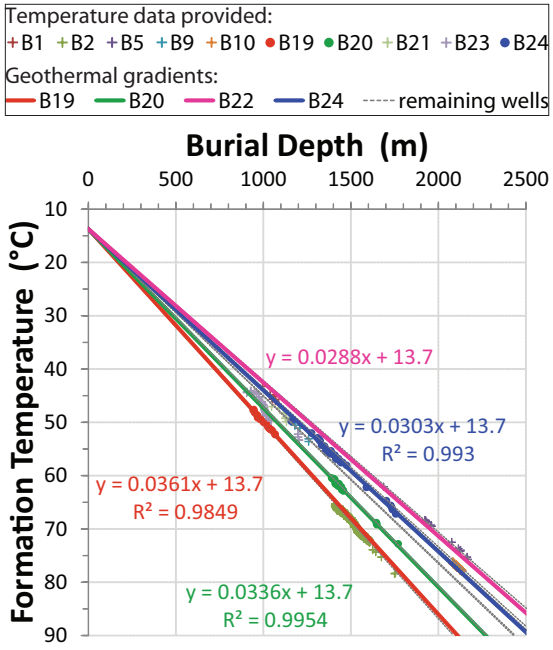

Figure 7–16 The four wells of interest cover a wide range of geothermal gradients. The gradient for well B22 was triangulated from temperatures of the 3 closest wells (see text).

Salinity Formation water salinity of marine sediments may decrease with depth as it is progressively diluted by meteoric aquifer water (*e.g.* Neglia 1979, Hanor *et al.* 1994a & 1994b). However, the dense network of negatively charged clay minerals in mudstones acts as semipermeable membrane that partially or totally fractionate ions dissolved in the pore water (Kharaka & Berry 1973). This phenomenon hampers the entrance of saline brines and may resolve in passive salinity increase via membrane-filtration (Graf 1982). Likewise, dissolution of evaporite deposits can lead to substantial salinity anomalies as the solutes migrate upwards (Hanor *et al.* 1994a & 1994b). The latter has been recorded in the Neogene Nile Delta sediments from dissolving Messinian evaporites (Sayles *et al.* 1973, Bode & Sotelo 1978, Vengosh *et al.* 1994 & 2000) that are held responsible for the potential release of hypersaline brines at seafloor seeps and mudvolcanoes in the area (Huguen *et al.* 2009).

Unfortunately, there are no measured fluid salinities available from the wells under investigation, *i.e.* any salinity model applied remains hypothetical and input parameters can only be calibrated in terms of causality. This is a critical aspect of the later described saturation model as the salinity of formation water is inversely proportional to hydrocarbon solubility; a phenomenon commonly referred to as “salting-out” effect (*e.g.* Wiesenburg & Guinasso 1979, Price 1979, Søreide & Whitson 1992, Docherty *et al.* 2007).

Salinity estimations are usually performed from electrical logs since the interstitial brines of a water-wet formation provide a highly conductive electrolyte network that affects the bulk discharge of the inflicted electrical field (Zinszner & Pellerin 2007). A similar principle

is traditionally used to infer hydrocarbon saturations in gas or oil wet reservoirs where the reduced water is isolated. This may lead to very high formation resistivities because electrical discharge at low water saturation occurs via a network of apolar hydrocarbons and rock matrix (Tiab & Donaldson 2004). Either way, electric measurements allow for pore fluid characterisation only if the resistivity (or inverse conductivity) of the rock matrix is known. This parameter is usually expressed by the formation factor F which is the resistivity ratio between the brine saturated rock and the saturating brine (R0/Rw) and can be derived both experimentally and empirically as an intrinsic rock property (Zinszner & Pellerin 2007).

Experimental determination of the formation factor from core samples is labour-intesive and usually conducted on a small number of reservoir plugs as a benchmark for empirical F-factor models (Lyons & Plisga 2005). Such empirical models involve the famous Archie's (1942) equations that describe the electrical conductivity behaviour of clay-free rocks while the Waxman-Smits (Waxman & Smits 1968) and dual-water (Clavier *et al.* 1984) models and their derivatives account for the dual conductive pathways via pore brine and clay mineral exchange cations. All these models relate to a power law function between F-factor and porosity (Equ. 7f) that was first described by Archie (1942) and is based on experimental data.

$$F[\,] = \varphi^{-m} \qquad \textit{(7f)}$$

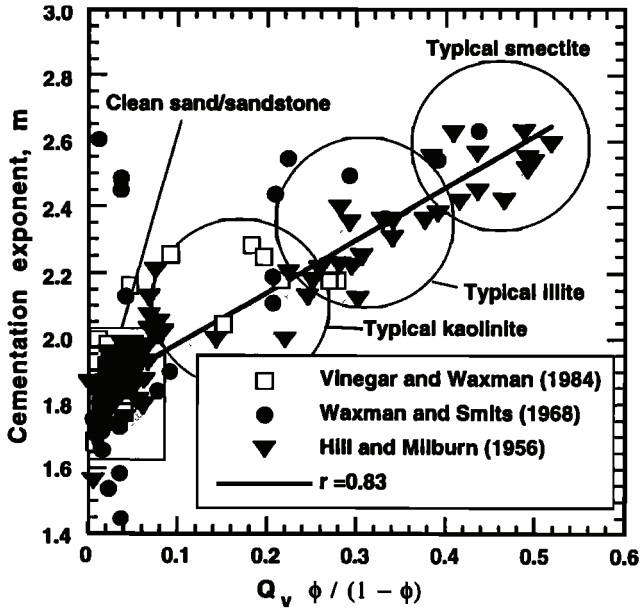

Figure 7–17 The cementation exponent m that determines the formation factor F can be calculated from excess surface charge Qv and void ratio. Qv can be determined from clay mineral content VSH via average clay mineralogy and the cation exchange capacity CEC of the respective mineral fractions (Table 7–11; see text). in other words, VSH is a key parameter to determine the formation factor which is essential for salinity calculations from resistivity logs (adopted from Revil *et al.* 1998).

Waxman & Smits (1968) related the so-called cementation exponent m of this equation to excess surface charge (Fig. 7–17), the latter being a function of grain density and cation exchange capacity CEC. Further, the effective CEC of any given mixture of sand grains and clay minerals is a function of clay mineral content VSH, relative fraction of each clay mineral type and its respective CEC (Patchett 1975; see Table 7A). It follows that the formation factor for each wireline log data point can be estimated if VSH is known.

VSH is traditionally derived from

natural gamma radiation logs (HSGR) on the basis of increased radionuclide concentration in clay-rich deposits (especially potassium-40 but also uranium isotopes; Ellis & Singer 2007) or the slightly less popular spontaneous potential (SP) logs that quantify clay content basically from the effective CEC of a sediment (Tiab & Donaldson 2004). Since SP logs are not available for the investigated wells of the study area VSH for evaluation of the F-factor is derived from HSGR logs under assumption of a fairly linear relation between natural radiation and clay mineral fraction (Ellis & Singer 2007; Fig. 7–18).

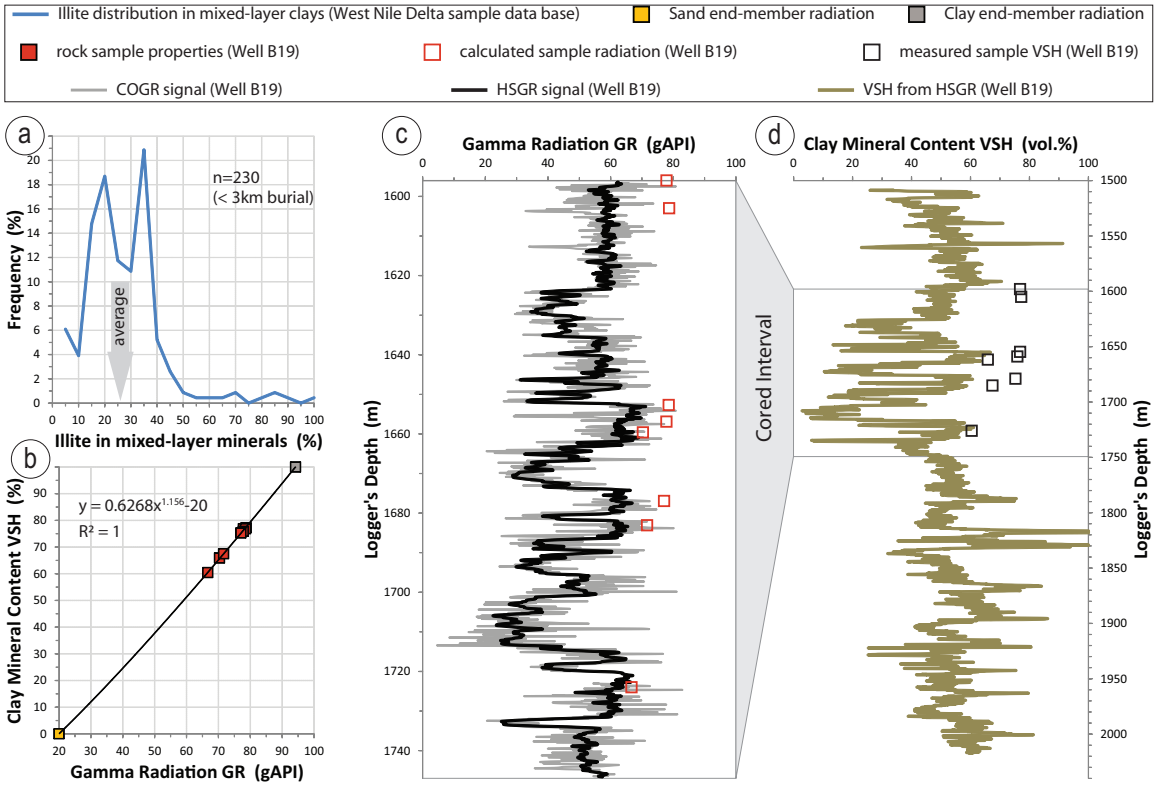

Figure 7–18 (a) The average Illite-to-Smectite ratio of 1:3 in mixed-layer minerals of Pliocene mudrocks from the western Nile Delta in conjunction with the average mineralogy and published clay mineral properties (Table 7A) allows (b) a strong correlation between VSH and gamma radiation. Although this relation itself is universal for the HSGR signals referenced to well B19 (c,d) the resolution of the output parameter VSH is clearly bound to the wireline log resolution (which has a significantly lower range and frequency compared to core gamma ray log COGR or core sample resolution).

The pervasive occurrence of clay-rich facies in the non-reservoir of the Pliocene borehole sections along with the aforementioned lack of calibration data demand the recourse to a published salinity model that both (1) accounts for the different behaviour of anions and cations in clay-bearing granular porous media and (2) was successfully tested *versus* measured data. Revil *et al.* (1998) provide such a model for electrical surface conductivity that yields pore fluid salinity as a function of temperature, water saturation, clay properties, and porosity. In principle, salinities from their model are derived from the ratio between (modelled) grain surface conductivities and (measured) bulk formation resistivity. The authors applied the method to boreholes in the Gulf of Mexico and output salinities were in agreement with sampled pore water, *i.e.* their model is expected to yield

realistic results that suffice for the purposes of this study. The exact procedure including further background information and references can be obtained from Revil *et al.* (1998). Key input parameters are listed in Table 7A.

	Illite	MLC*	Kaolinite	Chlorite	Reference
Fraction (g/g)	0.2	0.5	0.23	0.07	mudrock DB (n=230; unpublished)
Gamma Radiation (gAPI)	250	100	80	180	Ellis & Singer (2007)
CEC (meq/g)	0.09	0.62	0.03	0.01	Thomas (1976)

Table 7A Key parameters for the determination of the HSGR-to-VSH relation in Figure 7–18b and the subsequent calculation of excess surface charge Qv as a function of cation exchange capacity CEC and average grain density (~2650 kg/m³; see Revil *et al.* 1998, for further details). Qv and calibrated porosity yield an estimate for the cementation factor m (see Fig. 7–17) that is the key to formation factor F (see Equ. 7f), one of the most fundamental parameters in electric log interpretation such as Revil *et al.*'s (1998) salinity model. *mixed-layer clays with on average 25% Illite and 75% Smectite (see Fig. 7–18b)

As for the input water saturations an Archie-conform saturation log for the sandstone intervals (calibrated by Dr. Xiuwen Mo) was considered as an acceptable approximation because saturation effects on the applied salinity model are unlikely in mudstones due to their commonly weak response to electrical log signals. In fact, hydrocarbon saturation in mudstone pore space is irrelevant for electric salinity models for the same reasons why hydrocarbon saturation in mudstone pore space cannot be calculated from electric logs (see introductory part of Chapter 7). This is the strength of the saturation model applied in this study and discriminates it from other methods that are valid for conventional reservoir rocks only. Relevant input logs and the derived output salinity curves are shown in Figures 7–26 to 7–29.

7.3 From solubility to saturation

With apolar molecule structures, hydrocarbons are hydrophobic and therefore poorly soluble in water (*e.g.* Pedersen & Christensen 2007). While methane (C1) is the most soluble alkane, solubility decreases by a factor of 1.87 for each additional carbon atom (Brady *et al.* 1982). Since the composition of the Pliocene gas in the case study is strongly dominated by C1 (>98%; Part I) its solubility in pore water is crucial for the existence of a separate gas phase – *i.e.* gas saturation – as the bulk TG concentration decreases. In contrast, the volume loss of high gas concentrations to the formation water and *vice versa* – *e.g.* inside commercial reservoirs – will be negligible under the considered PT conditions (T<100°C; P<35 MPa; see Fig. 7–19), not least because of the diminishing solvent volumes.

Further, the sporadic traces of wet gas (C2+) within the case study have no physical impact on C1 solubility because short-chained hydrocarbon mixtures in water have ideal solution behaviour, *i.e.* the solubility of individual hydrocarbon components is a function

of their individual molar fraction in aqueous solution (de Hemptinne *et al.* 1998b, Dhima *et al.* 1998 & 1999). Consequently, the modelled TG can be approximated as pure C1 without risking significant errors in the modelled solubilities.

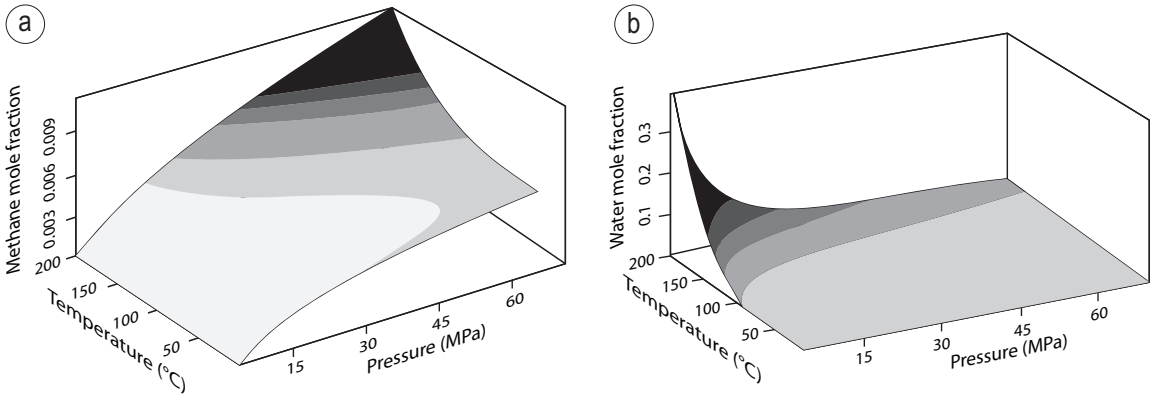

Figure 7–19 (a) Methane solubility in water and (b) water solubility in methane under various pressures and temperatures (adopted from de Hemptinne *et al.* 1998a).

First of all, determination of mutual phase solubilities requires the identification of effective partial pressures or fugacities of the substances involved. At equilibrium conditions, the fugacity of a chemical component such as methane in the gas phase is equal to its fugacity in the aqueous or dissolved phase (Equ. 7g).

$$f_{C1}^{HC} = f_{C1}^{aq} \qquad \textbf{(7g)}$$

The fugacity (in MPa) is an indicator for the chemical potential of a real gas. Substitution of the previously modelled or apparent pore pressure with methane fugacity expands the validity of the Ideal Gas Law to real gas behaviour under the given PT conditions. Therefore, identification of methane fugacity is not only fundamental to solubility calculations but also essential in determining the water phase volume that adds up to the methane volume to meet the associated porosity.

Phase fugacities under the environmental PT conditions are commonly calculated by an equation of state (EOS). The two-constant Peng-Robinson cubic EOS (PR-EOS; Peng & Robinson 1976) proved to yield particularly accurate values if compared to measured fugacities (*e.g.* Søreide & Whitson 1992, Dhima *et al.* 1998 & 1999). Consequently, the PR-EOS was used to calculate methane fugacity f_{C1}^{aq} in water according to the critical component parameters and accentric factors listed in Søreide & Whitson (1992). Subsequently, the pore volume occupied by methane molecules could be calculated by the pressure-corrected Ideal Gas Law. The remaining volume V_{H2O} – occupied by water molecules – was converted into molar units (n_{H2O}) via temperature-related water densities ρ_{H2O} (in g/m³; from Wagner & Pruss 1993) and molar mass M_{H2O} = 18.015 g/mol.

$$n_{H2O}\,[mol] = V_{H2O} \cdot \rho_{H2O} / M_{H2O} \qquad \textbf{(7h)}$$

This procedure yields the two most fundamental input parameters for solubility calculation, *i.e.* the molar methane concentration and the molar water concentration within the pore space of any unit rock volume along the Pliocene well sections. The free methane gas phase and hence saturation for each data point is calculated by subtracting the molar methane fraction x_{C1}^{aq} (in mol/mol) that is dissolved within the water. The magnitude of x_{C1}^{aq} is described by Henry's Law (Equ. 7i) as a function of the methane fugacity f_{C1}^{aq} in water (as derived from the PR-EOS), Henry's constant H_{C1}, and the activity coefficient γ_{C1}.

$$f_{C1}^{aq}\,[\text{MPa}] = x_{C1}^{aq} \cdot H_{C1} \cdot \gamma_{C1} \qquad \textit{(7i)}$$

Henry's constant H_{C1} is the fugacity of methane at infinite dilution in water and can be obtained from the relation of Harvey (1996) as a function of temperature and pure water saturation vapour pressure. The latter is given by Saul & Wagner (1987) and Wagner & Pruss (1993). Pressure correction for H_{C1} is conducted via the Krychevsky-Kasarnovsky or [K-K] equation (Krychevsky & Kasarnovsky 1935). Prerequisites for solving the [K-K] equation are determination of the pure water vaporisation enthalpy (*e.g.* from Yaws 1999) as well as molar C1 volume at infinite dilution as given by the expression of Lyckmann *et al.* (1965). Dhima *et al.* (1999) report that both Harvey's (1996) and Lyckmann *et al.*'s (1965) formulae yield values that are in excellent agreement with their experimentally obtained data.

The [K-K] equation (not shown) neglects the low water compressibility and assumes that the activation coefficient of Henry's Law is equal to one. This approximation was reported to yield valid results if (1) the [K-K] equation is applied at temperatures below 100°C (Malinin 1974, Dhima *et al.* 1999), and (2) if Henry's Law is applied to two-phase hydrocarbon-water mixtures due to their tendency towards ideal solution behaviour (de Hemptinne *et al.* 1998b, Dhima *et al.* 1998 & 1999). Calculation of methane solubilities in a unit volume of pore water is therefore a straight forward task using the following simplification of Henry's Law:

$$x_{C1}^{aq}\,[\text{mol/mol}] = f_{C1}^{aq} / H_{C1} \qquad \textit{(7j)}$$

A correction for the effect of dissolved salts in the formation water can be obtained by Søreide & Whitson's (1992) regression of Cramer's (1984) dimensionless salting-out coefficients k_s as a function of temperature. The molar methane fraction in brine x_{C1}^{brine} is finally calculated by the following expression (Søreide & Whitson 1992):

$$x_{C1}^{brine}\,[\text{mol/mol}] = x_{C1}^{aq} \cdot 10^{-k_s \cdot c_{sw}} \qquad \textit{(7k)}$$

where the salinity c_{sw} is in units of 10^3 mol/kg. The pure water density regression of Wagner & Pruss (1993) allows the required unit conversion of the input salinities that were originally modelled in mol/L (Chapter 7.2). Further, the obtained values for molar

methane solubility x_{C1}^{brine} are multiplied with the molar concentration of water n_{H2O} (Equ. 7h) in the remaining pore space to obtain the maximum amount of dissolved methane TG_{SOLX} (in mol/m³). Substitution of the pore pressure with methane fugacity in the Ideal Gas Law (Equ. 7b) enables the subsequent conversion of molar TG_{SOLX} into the volumetric solubility threshold TG_{SOL}:

$$TG_{SOL}\ [m^3/m^3] = TG_{SOLX} \cdot R \cdot T / f_{C1}^{aq} \qquad \textit{(7l)}$$

Likewise, Equation 7l allows the original molar TG_{model} concentrations (as obtained from the methodology in Chapter 7.1) to be recalculated into volume fractions of bulk rock.

As a reminder, a free gas phase is present if methane concentrations exceed the expected solubility. In other words, if more gas has been detected within the available pore space than could possibly be dissolved within the accessible volume of water a free gas phase would co-exist next to methane-saturated formation water. Consequently, since TG_{model} concentrations relate to the bulk rock volume the calculation of free (methane) gas volume SAT_{HC} per pore space φ in a unit volume of rock is as follows:

$$SAT_{HC}\ [m^3/m^3] = (TG_{model} - TG_{SOL}) / \varphi \qquad \textit{(7m)}$$

If less TG is available than could be dissolved the 'undersaturation' SOL_{HC} of methane in water can be expressed as a fraction of the solubility threshold TG_{SOL}:

$$SOL_{HC}\ [m^3/m^3] = TG_{model} / TG_{SOL} \qquad \textit{(7n)}$$

Equations 7m and 7n yield the ultimate target logs of this chapter.

Evaluation of results The herein deduced hydrocarbon saturation model can be applied independent of input data resolution because (1) the TG_{model} function in Chapter 7.1 was established on the basis of a scale-independent correlation between nuclear log signals and molar gas concentration, and (2) because the methane solubilities are calculated as molar fractions of water that are dependent on the same unit volume of porous rock as the TG_{model} concentration. In other words, a sampling step of one data point per

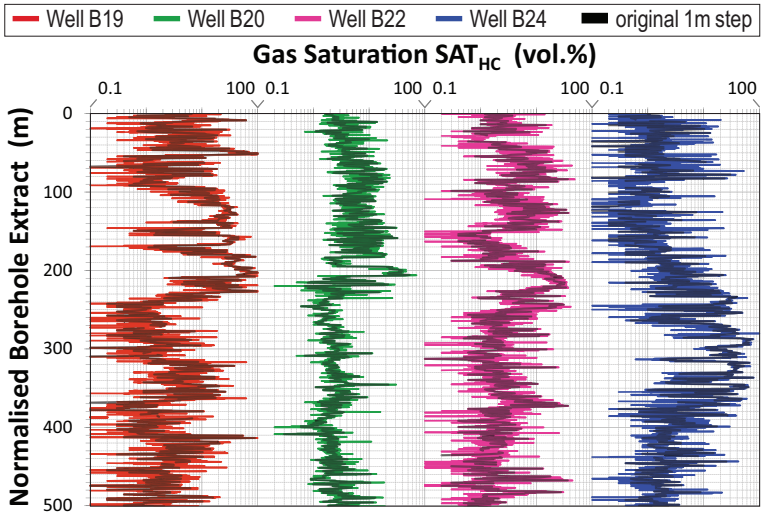

Figure 7–20 Modelled saturations at the original mudlog resolution (1m resampled input log signals) also represent the average of the output saturations calculated at the log resolution (~15cm) because model validities are scale independent (see text). Minor discrepancies in this Figure are due to the fact that the original TG model is not based on the moving average but on the static average for every full metre.

metre (as originally used in for the TG model and saturation model) yields the average saturation value of 1m wireline log saturation (~15 cm step; Fig. 7–20). Consequently, evaluation of the saturation model is based on the log resolution.

Remarkably, the model sensitivity in the range of the saturation threshold is above average (Fig. 7–21). This observation may be traced back to the diminishing influence

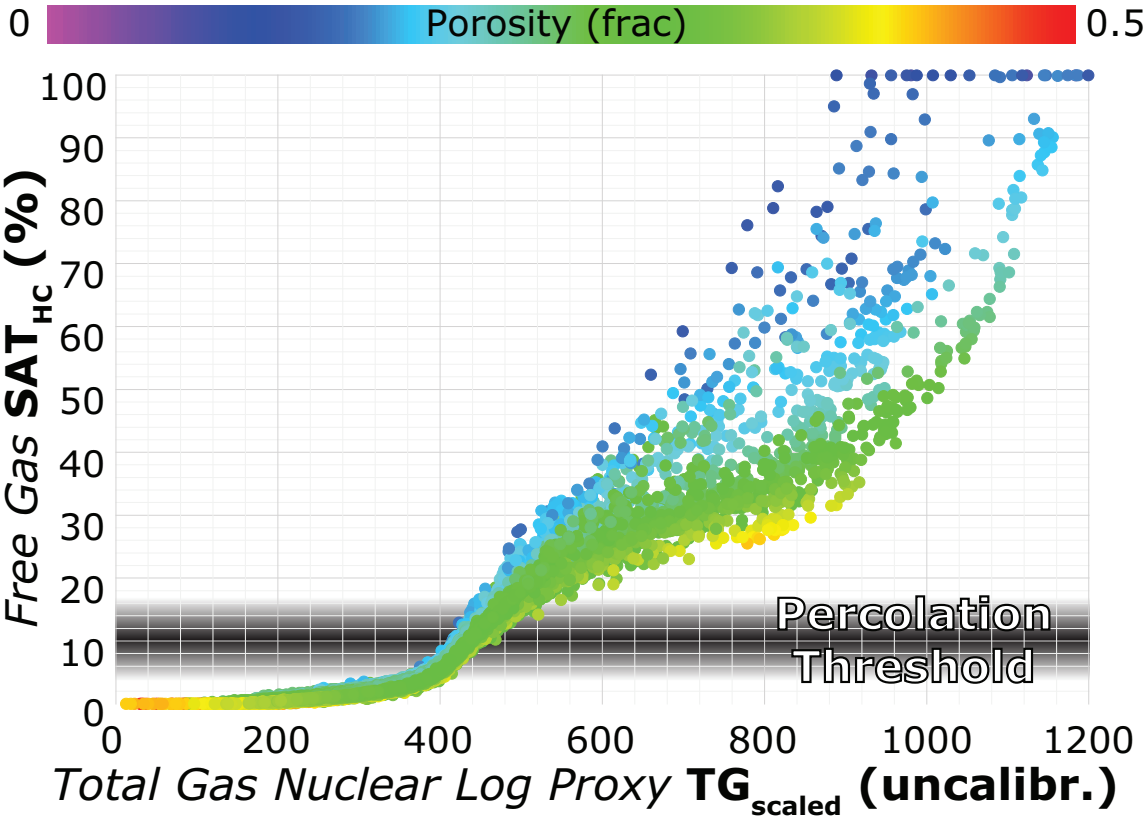

Figure 7–21 The kink in the conversion function from scaled nuclear wireline proxies (TG_{scaled}) with respect to the TG GC distribution (see Figs. 7–9b and 7–10) relates to modelled gas saturations (SAT_{HC}) in brine that covers the range of the percolation threshold (range of interest; see Chapter 6 and Fig. 6–1). The slope within this range is steeper than elsewhere, indicating a higher sensitivity of the wireline proxy possibly due to the largely missing interconnectivity of gas bubbles (Chapter 6).

of isolated gas bubbles on the nuclear wireline log proxy as opposed to interconnected gas phase at higher saturations, *i.e.* the TG log proxy may not be as phase-independent as initially assumed.

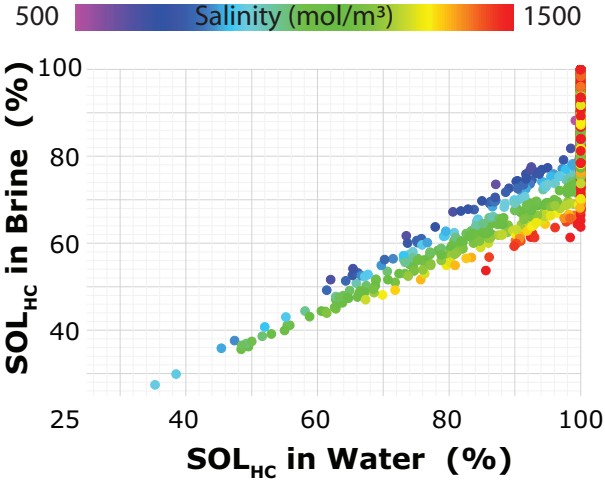

Figure 7–22 The salting-out effect of NaCl on methane pushes the gas concentration that would be totally dissolved in pure water past the saturation threshold at SOL_{HC} = 100%.

The magnitude of the salting-out effect as illustrated in Figure 7–22 emphasises its role as a key parameter for the detection of free gas phases at very low methane concentrations. Modelled gas saturations in the non-reservoir pore brines cumulate below the range of the solubility threshold (Fig. 7–23), *i.e.* Darcy flow may

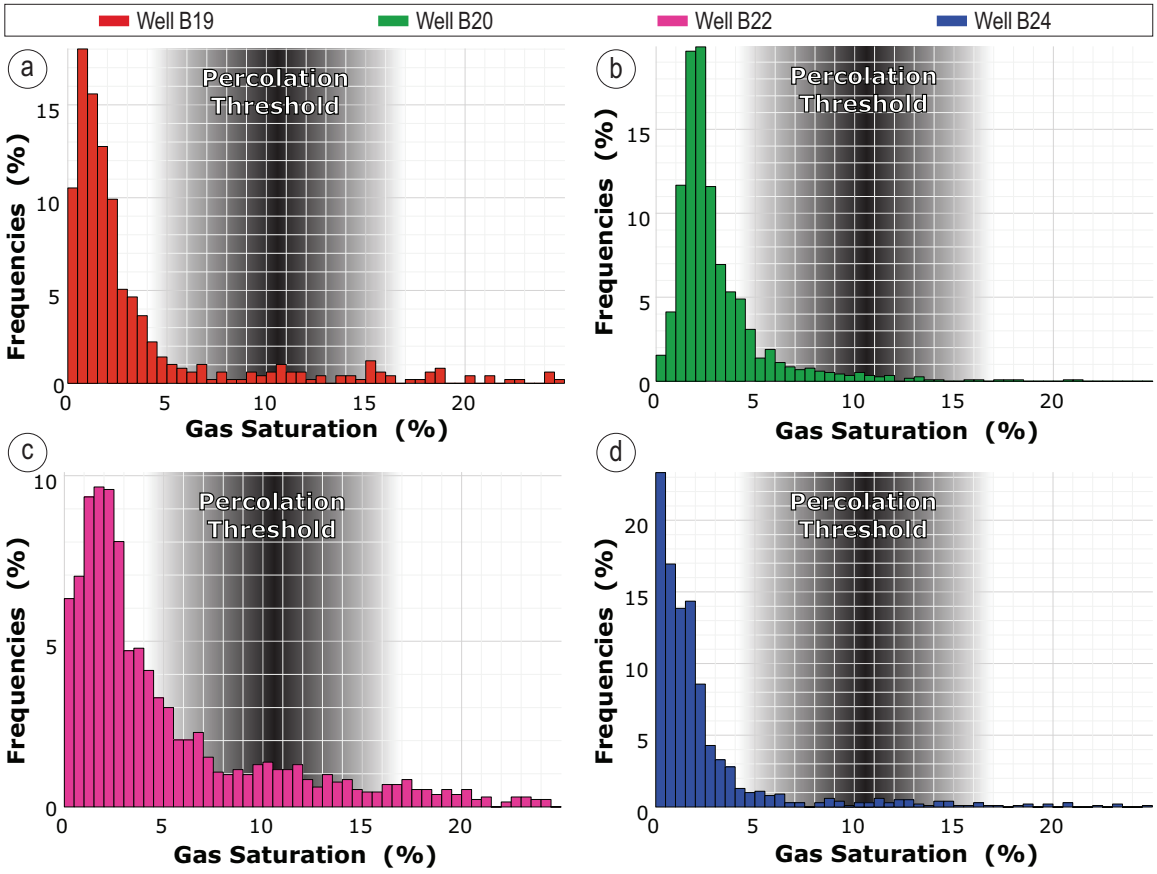

Figure 7–23 Gas saturations within the cap rock mudstones (facies 1-4) of the investigated wells cluster at values between 0 and ~6 vol.%. The bulk of the data plot below the percolation threshold (see Chapter 6) which precludes Darcy flow at wireline log resolution (~15cm).

only occur at a significantly higher resolution than that covered by the wireline log signals (Fig. 7–24).

The relative pore volume of brine-dissolved gas is amazingly rigid (Fig. 7–25) given the variability of the modelled environmental input parameters from Chapter 7.2 (see also Figs. 7–26 to 7–29). Such low variance of total dissolved gases indicate that the output quality of the proposed model approach is largely a function of the calibrated TG log (Chapter 7.1). It is therefore concluded that a commercial application of the saturation model would demand a more fundamental (laboratory) study on the interrelations between hydrocarbon concentration and nuclear responses (neutron/gamma scatter) similar to the work of Archie (1942).

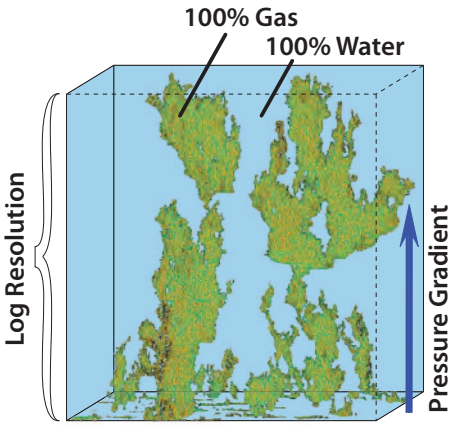

Figure 7–24 Small-scale heterogeneities in the spatial distribution of free gas filaments in mudstones cannot be resolved with conventional wireline log data. The model cube illustrates filamentary invasion of a water-wet host rock with petroleum while the pore pressure exceeds the capillary forces (courtesy of K. Kurtev).

Modelled input/output logs and relevant calibration data are shown in Figures 7–26 to 7–29. Combination of such estimated gas volumes with the geochemical gas proxies (Part I) allows the spatial and therefore causal association of genetic gas volumes with

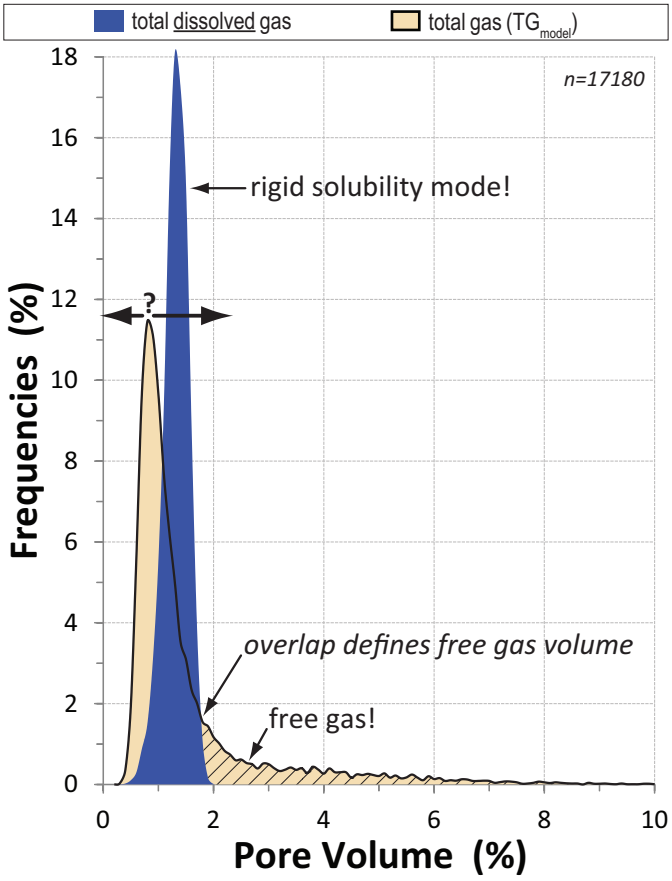

Figure 7–25 The volume of total dissolved gas across the investigated mudrock stratigraphy (4 wells, facies 1-4) is confined between about 1-1.5 %, i.e. largely independent of burial depth (see text). Hence, the quality of the input TG logs is more sensitive to the resulting free gas volume (i.e. gas saturation; hashed area) than reliability of other input parameters (see Chapter 7.2). Distribution plot with frequencies normalised to the total sample number.

their lithological (Part II) and seismic background. Such integrated approach provides the backbone of reconstructing the regional gas migration history (Part IV).

Synopsis of Chapter 7 Designed for reservoir rocks such as sandstones and carbonates, classic empirical wireline models for hydrocarbon saturation are not suited for clay-dominated cap rock sections. The approach presented in this chapter suggests an alternative method that involves total gas (TG) modelling from nuclear logs and its solubility in the formation brine. After treating the input data with a couple of standard procedures (Chapter 7.3) the application of Henry's Law resolves the solubility of methane in brine. A free gas phase is present if methane concentrations exceed the expected solubility, and the saturation is the free gas phase per pore volume.

The calibrated saturation model is scale-independent and implies that free gas occurs in most of the clay-dominated non-reservoir sections. The model resolution is not sufficient to capture a potentially filamentary network of free gas phase within the mudrock pore space that would allow relatively rapid leakage via Darcy flow. Implications on the potential of natural gas migration through the mudrock pore space of the investigated wells are discussed in Chapter 8 (Part IV).

Part IV – Data Integration: Controls on Migration

So far a range of different physical and chemical information has been integrated for calibration and propagation of geological properties such as porosity, clay content, gas concentrations, and geochemical fingerprints.

As a consequence, four wells with superior data coverage (Chapter 1.2) are now equipped with refined information about their geological profiles, gas volumetrics and relative fraction of migrated thermogenic hydrocarbons. Further, it was concluded in Chapter 3 that only the spatial distribution of wet gas biodegradation patterns along the sampled thermogenic/microbial gas profiles has the power to indicate the prevalent migration mechanism of the admixing thermogenic fraction.

This final thesis part deals with the interpretation of gas geochemical signatures under consideration of stratigraphic, lithological, and gas volumetric information. It will be demonstrated that such a synthesis of the standalone wellsite data analyses from Parts I-III uncovers migration pathways and mechanisms within the Horus and North Alex case studies as introduced in Chapter 1.2.

Chapter 8 Fluid flow in a regional stratigraphic context

The various direct and indirect implications on physical, chemical, and microbial processes that accompany natural gas generation, migration, and entrapment in the subsurface have been introduced, analysed, and partially quantified in the previous chapters. It is now to gather the derived information and convert it into well-specific and case study-specific interpretations of local migration routes, rates, and mechanisms in the western Nile Delta fan. The following paragraphs briefly describe how the gas geochemical information from Part I will be implemented and displayed along the borehole intervals in order to facilitate the integration of the different fluid flow indicators into a coherent migration scenario. The legend for the subsequent graphical illustration of the deduced processes is displayed in Figure 8–1.

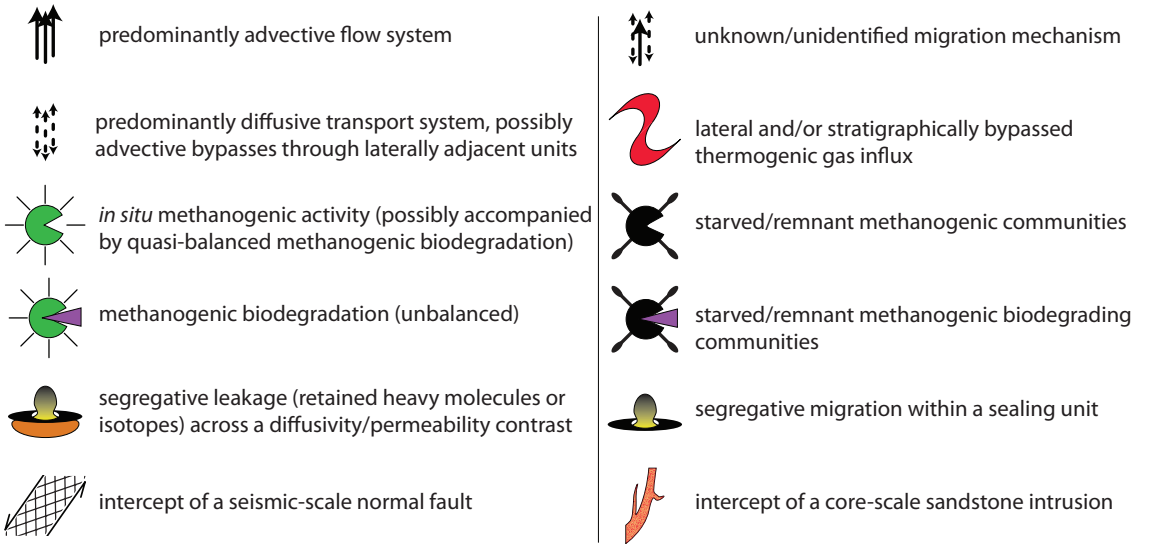

Figure 8–1 Legend for the various natural gas migration and generation processes that were identified through the integrated well-by-well analysis. See Chapter 3.2 for definition of/discrimination between quasi-balanced and unbalanced (or normal) methanogenic biodegradation.

Primary gas mixtures Migration analysis is about changes of hydrocarbon chemistry and volumetrics in both time and space. A temporal snapshot of primary gas mixing trends along vertical borehole trajectories is readily provided by profiles of the gas genetic analysis from Chapter 3. For example, dilution of a relatively thermogenic fingerprint within a given depth interval can be read from upwards directed increase of the microbial gas fraction. Moreover, merging of the genetic information with the gas saturation profiles from Chapter 7 provides thermogenic gas volumetric profiles that indicate the minimum amount of *ex situ* gases in the pore space. The scale discrepancy between gas and log data sets has been overcome by linear interpolation between the depth-synchronised gas sample locations to provide a rough optical guide for the identification of thermogenic ponding structures.

Discrimination between mixing mechanisms Further, prior to discussion of the well-site data sets from Well B19, B20, B22, and B24 it must be outlined how the two identified mixing trends ("dry" *vs*. "wet" in Chapter 3) are discriminated on vertical gas profiles. As a reminder, mixing of unaltered thermogenic hydrocarbons with *in situ* methanogenic gas is represented by a straight trendline between thermogenic and microbial end-members in a $\delta^{13}C1$ *vs* $\delta^{13}C2$ diagram (*e.g.* Fig. 3–15). In contrast, an explicitly "dry" mixing trend is characterised by strong to moderate biodegradation fingerprints (both isotopic and compositional) that could either be associated with a diffusive-metabolic process or advective migration (and leakage) of hydrocarbons that were geochemically overprinted at the gas-water contact (GWC) of accumulations. It was argued in Chapter 3 that an interpretation of the "dry" mixing trend must be performed in the context of vertical gas profiles along the affected borehole intervals.

Due to the yet unresolved generic processes that lead to the development of the "dry" mixing trend it was decided for a rather pragmatic discrimination that is based on conservative boundary conditions (Equ. 8a-b) for the patterns that were previously discussed in Figure 3–15.

$$\delta^{13}C2_{dry}\ [‰] > 0.051 \cdot x_t - 31.75 \quad | \quad x_t\ [\%] \in \{35,70\} \qquad \textit{(8a)}$$

$$(C2/C1_t)_{dry}\ [ratio] < 0.02 \quad | \quad \delta^{13}C2 > -40\ ‰ \qquad \textit{(8b)}$$

Equations (8a) and (8b) consider that a discrimination of the anomalous "dry" trend from the more common advective trendline is not possible for data points that plot in close proximity to the mixing end-member properties because of the inevitable trendline convergence (Fig. 8–2).

The relative magnitude of the anomalous dry trend can be quantified by the deviation of its $\delta^{13}C2_{dry}$ values from an average "wet" slopeline (Equ. 8c represented by dashed grey line in Fig. 8–2).

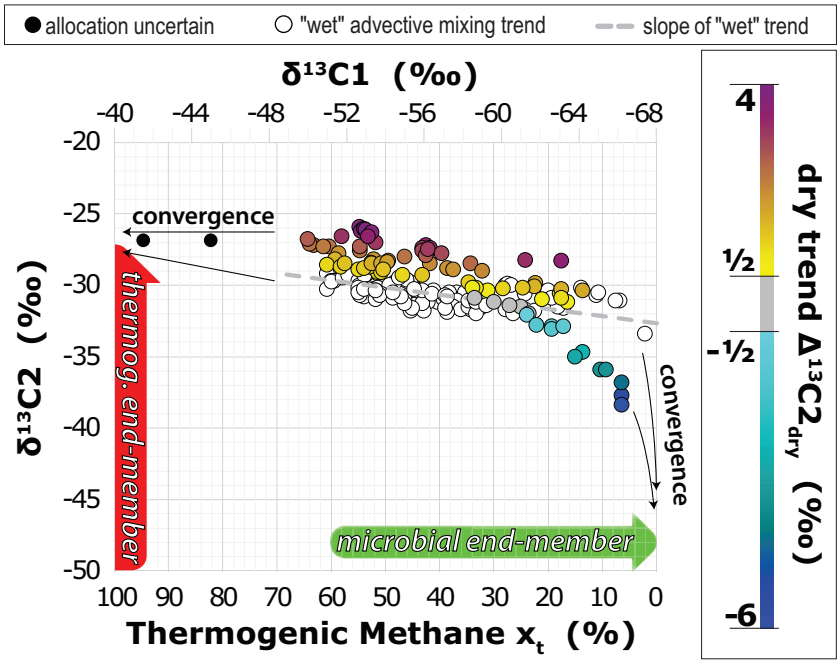

Figure 8–2 Isolated "dry" gas genetic mixing trend with colour-coded magnitude of $\Delta^{13}C2_{dry}$ offset relative to the average slope (dashed grey) of the normal advective trend (white circles). Trend discrimination is based on Equations (8a) and (8b) and subsequent $\Delta^{13}C2_{dry}$ magnitude estimation is according to Equation (8c). Two data points (black circles) were not allocated to either of the two trendlines due to their convergence at high thermogenic gas content.

For consistency reasons this reference slopeline is drawn parallel to the boundary condition from Equation (8a). Positive deviations represent biodegraded C2 since the associated $\delta^{13}C2_{dry}$ are heavier than expected and negative deviations stand for steep mixing gradients (thermogenic gas intruded into methanogenic controlled environment).

$$\Delta^{13}C2_{dry}\,[‰] = \delta^{13}C2_{dry} - (0.051 \cdot x_t - 32.75) \qquad \textit{(8c)}$$

Biodegradation proxies and segregative migration An additional benefit from the above procedure is that ethane biodegradation which is pervasive enough to leave a carbon isotopic imprint is readily picked up by positive $\Delta^{13}C2_{dry}$ values from Equation (8c) and Figure 8–2.

However, as concluded in Chapter 3 it must be considered that the molecular contribution of microbial ethane and propane is negligible and that molecular ratios are more sensitive to low or moderate wet gas biodegradation than shifts in the affected carbon isotope ratios. Further, almost constant δ^{13}C-iC4 ratios and the excellent applicability of the primary gas genetic end-member model suggest an overall very narrow thermal maturity range in the western Nile Delta Plio-/Pleistocene gases. The combination of all these findings supports a reasonable assessment of the relative ethane to propane biodegradation activity by changes in the $C1_t$, C2, and C3 molecular volume fractions.

A discrimination between such molecular biodegradation fingerprints from segregative removal of large alkane molecules by differential adsorption and/or diffusivity (see Chapter 2.3) must be performed in the spatial context of molecular trends as will be subject to case-specific interpretations in the following well-by-well discussions.

8.1 Migration scenario along Well B19

The combined wellsite data set of Well B19 is presented in its seismic context in Figure 8–3. The link between text and borehole profiles (*i.e.* figures) is hereafter provided by indexed markers or "flags". A first impression is that the gas genetic ratios along B19 are overall very constant in both channel reservoir and non-reservoir sections.

Sub-reservoir section A consistently dry and heavy $\Delta^{13}C2$ fingerprint throughout the bottom 80m interval implies the advective passage of gases that have received its biodegradation overprint within deeper accumulations. Accordingly – and following the conclusions from Chapter 7 – the steady increase in both thermogenic fingerprint and wetness towards flag series a (Fig. 8–3) is interpreted as a backfilling of migrated thermogenic gases within a conductive filamentary hydrocarbon network that spreads across

the pore space of this mudrock interval. In contrast, the carrier bed marked by flag a1 is allocated the function of a buffer and/or source for the static gas genetic ratio in the overlying sub-reservoir section. Isotopically biodegraded (flag a2) and methanogenic (flag a3) but compositionally rather enriched wet gas (flags a4-5) with yet still dry and heavy $\Delta^{13}C2$ imply that influx of thermogenic gases from lateral sources is sustaining *in situ* methanogenic biodegradation activity. Supply rates will be larger than microbial metabolic rates since the $\Delta^{13}C2$ proxy soon recovers its wetness (flag b1) and supplies another methanogenic biodegrading community (flag b2). There are no pronounced carrier beds in this interval (1210-1240m) so that a more proactive re-charge with thermogenic wet gases from lateral migration routes is considered unlikely.

The low geochemical variability is accompanied by minor gas pockets and eventually disrupted during the passage through a minor carrier bed at 1193m (flag c1). It is apparently host to C3 and nC4 biodegraders (flags c2-4) whereas light oil is less affected and the compositional dryness thereby passively enriched (flag c5-c6). The local biodegrading community at flag series c may receive additional hydrocarbon/nutrient influx from a subjacent fault zone (at ~1200m burial depth).

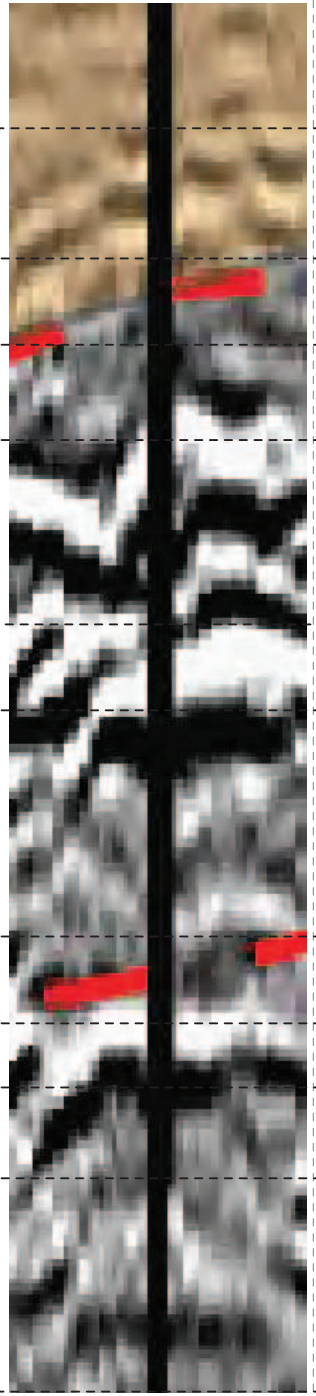
Further upwards, a 40m interval between flag series c and flag d (1155m bural) shows a succession of stacked thin beds which could be part of a levee geobody. Here, background gas saturations are accordingly elevated and spiky and molecular biodegradation patterns from flag series c do not stabilise until saturations drop across the supposed levee crest (flag d). The remaining interval up towards the reservoir base (~90m) is characterised by a monotonous mudrock lithology with gas saturations that are almost consistently below the model resolution (Chapter 7) and a progressive decline in wet gas components. The latter observation may suggest that thermogenic gas migration is possibly accompanied by quasi-balanced methanogenic biodegradation (see definition in Chapter 3.2) considering that the thermogenic fingerprint remains consistently high.

Channel Reservoir The ultimate reservoir base layer (flag e1) bears unequivocal evidence of unbalanced methanogenic biodegradation (flags e2-4) at the GWC. However, if an active biodegrading community coexists with local peak wet gas concentrations (flags e5-7; upwards decreasing biodegradation signature) the microbes must be supplied by the channel base layer via lateral migration. Since Well B19 has been drilled near the structural crest of the reservoir it stands to reason that these crestal hydrocarbons are subject to later migration from the adjacent flanks by density-driven circulation along the inclined sandstone beds. Appart from wet gas molecular gradients that spread across the main compartment of the hydrocarbon column (~40m topped by flag f5) such an

additional nutrient supply route may have secured the long-term sustainability of the local biodegrading community. This impression is supported by the injection of previously biodegraded gas high up into the overlying stratigraphy as will be described later in the text. The change in molecular composition (f5) near a local saturation minimum (f1) confirms the vertical reservoir compartmentalisation by clay-rich interlayers. The latter may be associated with elevated microbial activity (f2-4; heavy isotopes).

Overlying reservoir compartments (1030-960m) comprise slightly diminished saturations with a strong molecular and isotopic imprint from the basal microbial mediation. Such low-gradient profiles suggest a density-equilibrated hydrocarbon column. Leaking gases that were sampled from the top seal are expected to carry this inherited microbial overprint.

Top seal In fact, near the transition from sandstone-dominated facies to thin-bedded facies at the reservoir top (g1) there is a vague wet gas maximum (g2) with shallow gradients stretching from 100m below to 50m above and well across the cap rock interface. As the downwards depletion is inherited from biodegradation at the reservoir base the upwards decline must be coupled to progressive molecular segregation upon advective intrusion into the top seal. Consequently, a slight baseline elevation of the intruded thermogenic gas fraction by 5-10% (flag h) can be explained by the absence of a wet gas fraction which leaves vacant adsorption sites to $^{13}C1$ (Friedrich & Jüntgen 1972). It must be reminded that heavy carbon isotopes are enriched in the thermogenic gas relative to its methanogenic counterpart, and since the model for the gas genetic mixture is a direct function of $\delta^{13}C1$ (see Chapter 3.3) it is consequently exposed to bias from effects of such preferential adsorption. In reality, the purely adsorbed methane fraction within the cap rock will be isotopically much heavier than the measured values because separate analyses of dissolved, free, and adsorbed gases require sophisticated microprobing procedures (Whiticar 2002). In this study, however, fluid samples were recovered from boreholes and are therefore unlikely to resolve but rather disrupt and flatten the strong isotopic gradients that stretch between (1) adsorbed thermogenic methane along the conductive high saturation filaments and (2) dissolved microbial methane in the interstices. Consequently, the degree of methane desorption upon sediment fragmentation during drilling remains unresolved in this study (see section about gas data quality in Chapter 3.1).



Apart from adsorption phenomena, monotonously high thermogenic gas ratios and a biodegraded "dry" $\Delta^{13}C2$ fingerprint in the B19 top seal imply that reservoir leakage is an ongoing process. Otherwise methanogenic activity would have introduced vertical gradients in methane and ethane carbon isotopic ratios, not least due to the lost ethane com-

positional buffer of the originally wetter thermogenic gas to methanogenic isotope shifts (see Chapter 3.4 and particularly Figs. 3–16a and 3–17a for background information). Moreover, an almost fully gas saturated carrier bed within the hemipelagite cap rock (flag i) further supports an active leakage scenario because its volumetric buffer-capacities are obviously expired. Herein accumulated gases do not bear any chemical overprints from lateral injection but clearly reflect the reservoir gas fingerprint.

8.2 Migration scenario along Well B20

In contrast to Well B19, its 11km south-east situated neighbour B20 (see Fig. 1–7) has a comparably low thermogenic gas content (Fig. 8–4) and the first impression is that absence of both strong genetic mixing gradients and biodegradation activity may severely hamper a detailed migration analysis.

Sub-reservoir section At the very base of the section, temperatures exceed the optimum methanogenesis window by 25°C (see Chapter 2.2). As no biodegrading activity can be detected at these depths it is assumed that local microbial communities either have a low metabolism rate or fell dormant. Most of the microbial methane at this level is consequently inherited from palaeo-methanogenesis under more adequate temperature conditions and has since been retained in the pore space with progressive burial until the well was eventually drilled. Thermogenic ethane and propane fraction ($C2/C1_t$ and $C3/C1_t$) are in agreement with these interpretations a direct function of thermogenic gas content at temperatures higher than 68-69°C. This relation is visible in the gas logs because there appears to be a weak thermogenic gas injection from lateral migration along thin beds at roughly 1720m (flags a1-2 and a4-5). An alternative explanation for the slight bulge in both isotopic and molecular thermogenic fingerprints could be progressive dilution of palaeo-entrapped thermogenic gases before its charge routes were cut-off. However, the presence of a presumably advective "wet" $\Delta^{13}C2$ mixing trend (flag a3) in conjunction with rather heavy and "dry" $\Delta^{13}C2$ above and below stands in favour of an active lateral injection scenario in proximity to flag series a; palaeo-entrapment within the by then optimum methanogen temperature window would have lead to meanwhile much lighter $\Delta^{13}C2$ from contemporary microbial ethane by-production. At the same time, the inferior thermogenic gas fraction and weak/absent molecular and isotopic gradients that can be followed over 150m upwards (1700-1550m burial) imply a large-scale equilibrated vertical migration scenario without lateral thermogenic re-injection. Absence of present-day microbial activity at these elevated temperature regimes hampers the identification of

the predominant migration mechanism – advection *vs*. diffusion. However, although there are far less sand-rich interlayers and associated gas pockets within the sub-reservoir section – as compared to the adjacent Well B19 – the overall background gas saturation of B20 mudrocks seems to be consistently higher by 1-2%. Still, it will remain unresolved to which extent these differences may arise from uncertainty artefacts in the applied saturation model (Chapter 7).

Minor changes in wet gas ratios such as segregative entrapment of ascending thermogenic gas components (*e.g.* flags b1-3) follows the deepest clear indicator for present-day microbial activity at 1570m (~66.5°C) where there is the base of a nC4-biodegradation trend (flag c2) in the vicinity of a thin bed with elevated saturation (flag c1). The hereby initiated departure of the molecular thermogenic fingerprint ($C2/C1_t$ and $C3/C1_t$) from the isotopic pathway of genetic gas mixture is amplified 20m higher by segregative wet gas loss (d2) through a slightly more pronounced bedding that has been picked up by the three-fold facies group recognition (from Chapter 5.3) as a muddy sandstone (d1). A present-day generation of microbial methane is affirmed within 100m below the reservoir due to an associated contrary development of molecular thermogenic fingerprints (increasing $C2/C1_t$ and $C3/C1_t$) and its isotopic counterpart (decreasing thermogenic gas fraction).

Channel Reservoir The highest reservoir gas saturations are located in a 10-15m thick zone near the channel base. The channel morphology is rather planar so there is no pressure exerted from a deeper situated leg of reservoir gas and the drilled hydrocarbon column is hence very close to the effective column height as it is commonly measured from crest to gas-water contact (GWC). The entrapped gases are quite consistently dominated by microbial methane that must have arrived from the microbial production sites in the clay-rich stratigraphy below the channel deposits. A "dry" and slightly enriched $\Delta^{13}C2$ fingerprint (flag e) is probably an isotopic overprint that was inherited from palaeo-biodegradation because the fermentation-resistant isobutane fraction in the bottom half of the channel (1340-1450m) is proportional to the dryness pathway as would be expected for unaltered gas mixtures. Consequently, dryness of reservoired hydrocarbons qualifies as a local measure for the thermogenic gas fraction and does so at a higher sampling rate than the genetic fingerprint that is modelled from $\delta^{13}C1$ measurements. According to this argumentation residual oil and thermogenic gas (~dryness, flag f) seem to be entrapped within an thick intra-reservoir mudstone section (1415-1425m) and may well represent a conserved molecular gradient from palaeo-biodegradation. Once the former supply routes of wet thermogenic gas were cut off the successive dilution with arriving

methanogenic gas overprinted such gradients in the more permeable units above and below via compositional equilibration.

Top seal The mudrock dominated top section of the channel (<1390m) and the lower hemipelagite cap rock host a succession of drying upwards trends (flags g2, h2, i2, j3) that are accompanied by upwards increasing C2/C3 ratios and/or iC4/nC4 ratios (flags g1, h1, i1, j2). Study of the core photographs revealed that filamentary sandstone dykes can be allocated to the bottom part of two of the affected intervals (Fig. 8–5). It is therefore likely that most of the identified gas chemical dilution patterns in this interval originate from thermogenic gas that is lost from subseismic-scale sandstone dykes. Consequently, large volumes of thermogenic gas from unknown origin currently bypass the cap rock section through sandstone intrusions. The fact that several of these small-scale features happen to intersect the coring trajectory implies that the entire local cap rock is at risk to be interveined which lead to substantial reservoir drainage. This scenario would explain the elevated gas saturations in the capping mudstones and both low thermogenic gas fraction and reservoir pay.

Figure 8–5 Subseismic-scale sandstone intrusions across the ultimate sealing unit of Well B20. The vesicular structures in the two shallower core images are interpreted as marginal intersects of dike structures while deeper cores show full cross-sections.

8.3 Resolving the Horus case study

The regional setting of Wells B19 (Chapter 8.1) and B20 (Chapter 8.2) within the Horus case study has been introduced in Chapter 1.2. Absence of pressure communication between the channel legs of Wells B19 and B20 was suggested to be due to the compartmentalisation by at least one sealing fault between the two reservoirs. The lack of recent fluid interchange between the two reservoir compartments is confirmed by the

fact that the gas genetic profiles of the involved well trajectories are very different: B19 is dominated by consistently high thermogenic gas fractions while B20 is controlled by microbial methane.

Further, underfilling of the B20 hydrocarbon accumulation as compared to B19, in conjunction with the small-scale sandstone filaments inside the B20 cap rock (Fig. 8–5) implies that the channel south of the fault (right hand side in Fig. 8–6) has been more prone to hydrocarbon leakage. In the literature, networks of sandstone dikes and sills that intervein mudrock intervals are usually considered as the result of a single hydrodynamic injection event (Vétel & Cartwright 2010, Vigorito & Hurst 2010, Szarawarska *et al.* 2010). It is understood that seismogenetic events such as earthquakes and bolide impacts can trigger liquefaction of overpressured sandstone compartments, and local disruptions of the sealing units where matrix shear strength is outbalanced by the internal pressure of the liquefied compartment may serve as starting points for instantaneous self-propagation of the grain/fluid mixture through opening fractures across overlying low-permeability units (see Cartwright 2010, for a brief review). However, as the exact physical emplacement procedure of seismic-scale intrusions is not yet fully understood it must be stressed that core-scale intrusions of a few centimetre thickness as in the case of the B20 seal interval are hardly even documented in the literature.

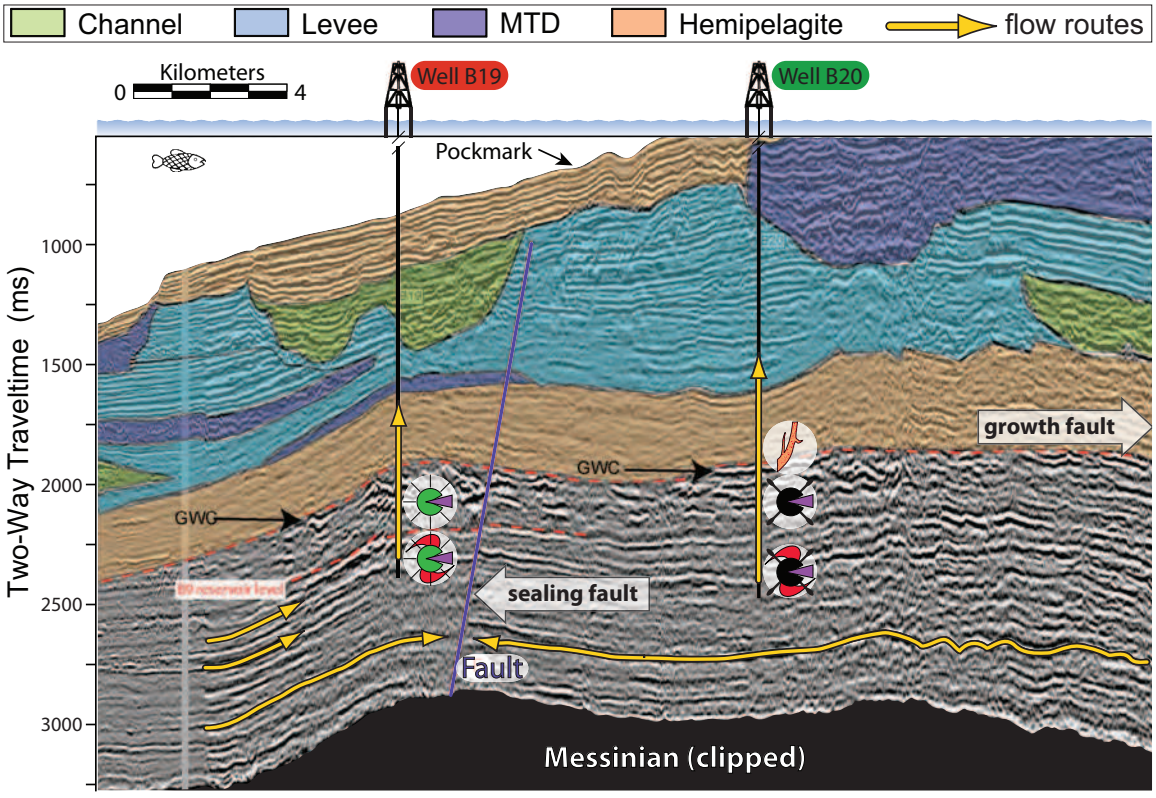

Figure 8–6 Migration scenario of the Horus case study (see profile line in Fig. 1–7). The southern (B20) leg of the channel has apparently lost large quantities of gas through the sandstone-intruded seal whereas the northern (B19) leg has largely retained its thermogenic and biodegraded reservoir gases because it was (1) shielded from possibly growth-fault related overpressures by an impermeable fault and (2) is actively recharged through basin-wards carrier beds. See Figure 8–1 for the pictogram legend and further descriptions in text.

Although present-day pore pressures within the channel compartments are close to hydrostatic conditions (see Figs. 7–26 and 7–27) the presence of sandstone injections in the overlying stratigraphy implies that overpressures once were severe enough to fracture the cap rock and emplace liquefied sands that originate from the channel deposits. The compositional palaeo-biodegradation trend that was preserved in a thick intra-reservoir mudstone layer along the B20 gas profile (see Chapter 8.2) confirms that the southern channel leg harboured a thermogenic gas accumulation prior to seal breach and subsequent reservoir drainage. The residual microbial gas within the B20 accumulation must therefore be in dynamic charge/leak equilibrium with the breached cap rock which precludes a complete refill of the structure with microbial gas. Further, the prevalent microbial gas composition implies that charge with thermogenic gas prior to the cap rock failure arrived from the basin-wards (northern) end of the channel and was permanently cut off when the fault in Figure 8–6 isolated the B20 leg from the B19 reservoir.

Further, it now appears conclusive that the mentioned normal fault plays a vital role in the hydrocarbon migration history of the Horus case study. A major regional growth fault (Rosetta fault) that strikes beyond the southern boundary of the available seismic block may have accumulated a sufficiently thick sediment pile that exerted unusually high overpressures within the permeable channel deposits. Emplacement or reactivation of the smaller fault in Figure 8–6 may have triggered the catastrophic release of overpressured sands through the top seal of the B20 channel leg and at the same time shielded the northern (B19) channel leg from such destructive pressure turnover. Instead, the presence of B19 seal gases that are geochemically indistinguishable from reservoired gases suggest that the pressure exerted by the hydrocarbon column at the structural crest must have once been sufficient to establish filamentary gas phase pathways through the mudstone pore network of the top seal. In other words, it is possible that local overpressures were sufficient to overcome the capillary entry pressure of the seal interval (especially at shallower burial when pores were less compacted) and thereby established the necessary gas saturations for a permanent advective release even at the present-day moderate reservoir pressures that would not suffice for initial capillary seal breach (see Chapter 4.2).

Considering the unknown palaeo-sealing capacities of fault zones in the Horus area the clues that are given from cap rock sandstone intrusions (Well B20) and presumably active seepage through the filamentary remnants of a palaeo-leak (Well B19) it is tempting to speculate that the channel reservoir has once been in pressure communication before tectonic displacements lead to the present-day compartmentalisation. Naturally, the B20-leg was breached by sandstone injections because it is in closer proximity to

the pressure source of the south-eastern growth fault. Still, distal pressures at the B19-location must have been sufficient enough to breach the capillary seal and thereby paved the way for the advective charge/leak system that can be seen today. Relevant events within the Horus case study are schematically summarised in Chapter 9.

However, the prevalent feeding pathway for the local pockmark (Fig. 8–6) remains unresolved. While it is not unlikely that accumulated gases inside the channel reservoir contribute to pockmark effusion the relative importance of fault-parallel migration *versus* seepage through the sandstone intruded cap rock between Well B20 and the fault-intersected channel site cannot be assessed on the basis of the available data. In general, fault-sealing capacities are a function of various structural, textural, and diagenetic processes (Eichhubl *et al.* 2005) that are briefly outlined during the assessment of the tectonically more fragmented North Alex case study (Chapter 8.6).

8.4 Migration scenario along Well B22

As the logged interval of Well B22 spans over more than 1 km it provides the most complete cross section through the Nile Delta Plio-/Pleistocene stratigraphy. This circumstance is due to the fact that the well was designed to penetrate a vertically stacked series of minor levee and channel reservoirs (Fig. 8–7). The first impression about its gas profile is that thermogenic fingerprints are concentrated at levels in the vicinity of the reservoir structures as opposed to overwhelming dilution with microbial methane in the intermediate mudrock intervals.

Deep accumulations The bottom accumulation (flag a1) with moderate thermogenic gas fingerprint is probably a sink for palaeo-methanogenic gases considering the elevated temperatures, absence of heavy $\delta^{13}C\text{-}CO_2$ (flag a3), and pristine thermogenic isotope ratios (flag a2). These observations are conform to the previously described evidence of a dormant or starved microbial community in a similar temperature regime at the base of Well B20 (Fig. 8–5). In B22 however the directly overlying 100m mudrock interval is suggested to harbour a methanogenic environment because isotopically light microbial ethane by-production is held responsible for a slight bulge in the "dry" $\Delta^{13}C2$ pathway. Independent of the question whether these admixed methanogenic gases originate from active or palaeo-production the thermogenic gas must pass this interval at extremely slow rates in order to acquire such a pronounced microbial imprint ("dry" gas mixing, see Figure 3–16), *i.e.* diffusive mixing and mechanical compaction are more likely to control local migration rates rather than the more effective advective flow.

The minor channel/overbank reservoir at 1830m (flag b1) is marked with vertically uniform molecular wet gas ratios and a predominantly „wet“ $\Delta^{13}C2$ trend (flag b2) that both imply well-mixed reservoir gases. Slightly elevated $C2/C1_t$ ratios (flag b3) suggest lateral injection of relatively wet thermogenic gas that is already diluted by deep palaeo-microbial gas since both wet gas content and thermogenic gas fraction further increase during the passage to the next shallower reservoir at 1730m. Here, elevated thermogenic saturations within both main reservoir body (flag c1) and associated thin beds imply a diminished microbial gas admixture which must result from a more pronounced lateral injection of thermogenic gas because here the first certainly methanogenic $\delta^{13}C$-CO2 fingerprint has been taken (flag c2). As a consequence of active background methanogenesis both dryness and gas genetic pathway proceed in a somewhat bulged trajectory towards the next thermogenic carrier beds 150m above (d1).

There is no indication of wet gas biodegradation within the lower half of the B22 profile, despite the fact that the thermogenically overprinted interval between 1550m and 1850m burial is within the required temperature limits. It is possible that the missing geochemical effects (*e.g.* flag d3) of local biodegrading communities are strongly diminished by lateral and advective arrival of large volumes of fresh wet gas. An equally likely explanation would be that thermogenic gas injection only happened recently by structural shifts in the regional basin architecture, *i.e.* the time-span between entrapment and sampling has been too short for the development of microbial overprints (charge rate exceeds biodegradation rate) or biodegrading microbial communities are simply absent. Either way, both scenarios would lead to the conclusion that thermogenic entrapment within the discussed interval occurred rather recently and is probably still in progress.

Inter-reservoir section The thermogenic gas anomaly that is declining across the overlying 300m mudrock interval (above flag series d) is marked by an almost synchronous exponential decline in thermogenic gas characteristics such as as methane carbon isotope ratios (proxy for genetic mixture), ethane carbon isotope ratios (represented by $\Delta^{13}C2$), and wet gas content (see related dryness curve in Fig. 8–7). A first but isolated biodegradation fingerprint (flag f3) is associated with a small gas pocket (flag f1) in the vicinity of a seismic-scale fault intercept (at ~1380m burial). This leads to a minor drag in the smooth decline particularly with respect to the $\Delta^{13}C2$ curve (flag f2). Otherwise the described large-scale decline in thermogenic signatures forms the counterpart of an inversed development that stretches from a thin-bedded accumulation at 1280m (flag g1) up to the lower reservoir boundary (flag i) and that is exclusive to the carbon isotopic ratios. As both isotopically light methane and ethane are associated with methanogenic

gas generation it is likely that the smoothly curved $\Delta^{13}C2$ decline, particularly above flag series f, reflects a dry diffusive admixture of the thermogenic gas into an active methanogenic source kitchen that is otherwise shielded from external contamination. Consequently, and in accordance to Figure 3–16 (Chapter 3.4), the steep $\Delta^{13}C2$ inversion trend that connects to the levee reservoir reflects a likewise diffusive admixture of leaking microbial gas (flag g1) and an extremely dry hydrocarbon column (flag series j).

Levee reservoir Here, remarkably uniform molecular gradients (flags j4-5) are clearly associated to methanogenic biodegradation (flags j2-3) of the reservoired gas. In fact, the biodegrading microbes appear to have migrated from the reservoir base 70-80m downwards into the underlying clay-rich sediments (flag h). These findings do not necessarily imply that the biodegrading communities have followed the GWC downwards because of reservoir overfilling: this is not the case as implied by regularly low saturations within the affected sub-reservoir unit. On the contrary, the huge biodegradation fingerprint within the the reservoir gas and the fact that even the rather fermentation-resistant ethane has been partly metabolised (heavy $\Delta^{13}C2$) indicates a highly stressed microbial community that is at the verge of starvation from a lack of charge with thermogenic nutrients. Since no similar phenomenon has been registered along gas profiles of other Nile Delta wells it is suggested that either (1) biodegrading microbes have an elevated metabolic activity that is driven by enhanced nutrient supply from organic rich mudstone layers of levee reservoirs or (2) the accumulated gas in the affected B22 reservoir structure has been cut off from thermogenic gas supply for a microbiologically crucial time period. Considering (1) the discussed missing advective link between the biodegraded shallow levee reservoir and – in terms of biodegradation – vital non-degraded deeper thermogenic gas accumulations and (2) the literature reports on metabolic restrictions as a common microbial response to diminishing nutrient supply rates (*e.g.* Tyler *et al.* 2004, Bouchard *et al.* 2008a,b; see discussions in Chapters 2.2 and 3.4) the drying-up scenario is preferred over a self-inflicted microbial overpopulation.

Top seal In addition to the implications of restricted or failed charge routes there is evidence of top seal leakage above the levee reservoir. Although propane and normal butane ratios slowly stabilise within the ultimate cap rock (flags k4-5) there is evidence of highly saturated thin beds (flag k1 and above) that harbour a thermogenic gas anomaly (flag k2) and a reservoir-alike ethane biodegradation signature (flag k3). Further, a gas saturation minimum at about 935m burial depth coincides both with a pronounced drop in relative thermogenic gas content (above flag l1) and the intercept of a seismic-scale

fault zone. All these features directly overly a very fresh thermogenic fingerprint (flags I4-7) with "wet" advective flow indicator (flag I3). The common occurrence of minimum gas saturation above unusually high-saturated cap rock thin beds, presence of leaked reservoir gases, and local injection of apparently bypassing undegraded fault-gases (flags I3-7) implies that the fault zone is vertically sealing but laterally conductive. This observation supplies the missing link to the processes that have stressed the biodegrading community to relocate downwards across the reservoir base.

Microbial proxies for charge/leak balance Before the present-day situation the metabolic rate of a local GWC microbial community must have been in adoptive equilibrium with the diffusive supply of low-molecular weight hydrocarbons downwards across a compositional reservoir gradient. Adoptive equilibrium means that the degree of re-charge passively restricted the metabolic rate and thus the size of the microbial population: higher charge rates steepened the compositional wet gas gradient and thereby increased nutrient supply (by elevated rates in diffusive/density-driven transport across the hydrocarbon column towards the base) and the GWC dwellers flourished, lower charge rates had the opposite effect and likewise forced the microbial community to adopt to diminished supply rates. Considering all the collected evidence what presumably happened in the B22 levee reservoir is that a catastrophic event drained most of the previously accumulated hydrocarbons inclusively the vital wet gas nutrients. It must have been an abrupt leakage event because at slower drainage rates the microbial population would have steadily declined as a function of equally steady decrease in the reservoir gas compositional gradient. However, abrupt nutrient restriction to a large microbial community has led to comparably quick depletion of the reservoired wet gas buffer and thereby induced the present-day inversed nutrient gradient downwards in the direction were the dissolved fresh gases arrive from the mentioned methanogen source kitchen. The molecular profile of the ultimate sub-levee interval indicates that the microbial community must have managed to relocate deeper into the sediment and closer towards their replacement nutrient source. It remains unresolved whether this is an active microbial migration process and/or passively supported by physical forces that arise from pore-scale processes such as strong compositional gradients. Either way, it should be noted that both methanogenic and biodegradation processes can play a vital role in deciphering (and influencing) hydrocarbon migration mechanisms.

Another implication of the Well B22 scenario is that reservoir-associated microbial communities require not necessarily stable but – on a microbiological timescale – consistently charged accumulations. Accordingly, widespread biodegradation would be a signature of

"conservative" petroleum systems that charge over a long time period via the very same well established migration routes. Another factor that would restrict or inhibit biodegrading activity is possibly a diffuse or non-equilibrated GWC, *e.g.* from relatively fresh or ongoing injections such as in the case of the deep thermogenic gas reservoirs along Well B22.

It is not suggested that the described scenario is a common survival mechanism of deep microbial communities that have lost their nutrient supply routes. However, the presented evidence for the physical ability of microbial relocation through fine-grained sediments sheds new light on the question how (and why!) microbes initially colonised the deep biosphere.

8.5 Migration scenario along Well B24

The gas genetic profile of Well B24 appears to be quite similar to the previous B22 section in so far as the thermogenic gas fingerprint is likewise focused around two vertically stacked maxima (Fig. 8–8).

Sub-reservoir section Two beds near the base of the well (flag series a) exhibit peak thermogenic signatures (flags a2,7-9) that imply a non-degraded source based on both pristine isotopic and molecular propane and butane ratios (flags a3,5-6). As the coarsest sandstone units contain almost 90% thermogenic gas (flag a2) that is neverthelss overprinted by remnant methanogenic fingerprints (relatively heavy $\delta^{13}C\text{-}CO_2$, flag a4) it must be assumed that a large thermogenic contribution is injected from adjacent bypass systems. The vague thermogenic peak at the deeper bed (~1740m) is probably stunted by dilution effects due to the limited volumetric resolution of the gas sampling techniques (~1m formation average; see Chapter 3.1). Further, steep butane gradients between the two sandstone beds at 1700m and 1740m (flag series a) imply some microbial activity in the intermediate mudrocks (probably thin beds) and support the idea that lateral charge rates exceed the vertical contribution in the vicinity of the well trajectory. By analogy with B22, the wet gas supply rate to these deeper thermogenic gas pockets is either generally higher than microbial metabolism and thereby whitewash any evidence of contemporary biodegradation or the system was exposed to recent episodic re-charge with a similar effect. Either way, lack of biodegradation suggests that the deep thermogenic gas was emplaced relatively recently and may still be subject to ongoing charge.

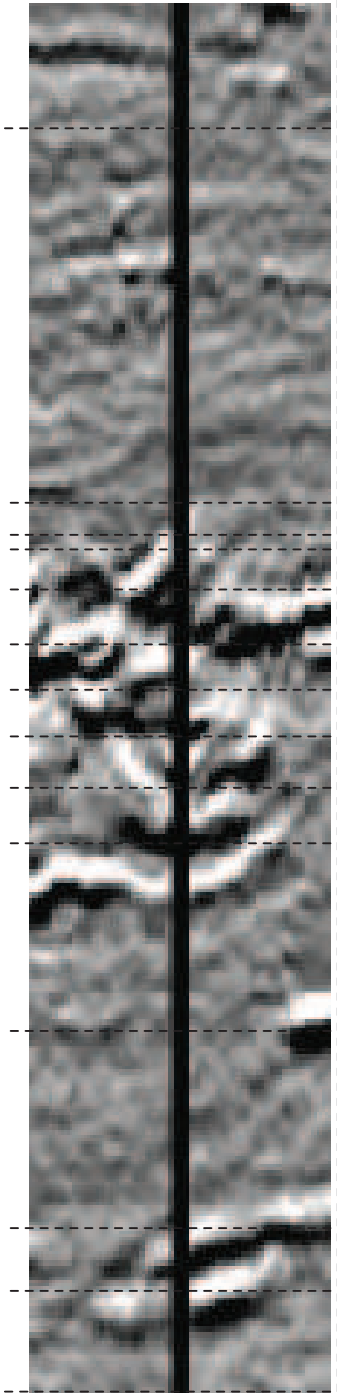
The thermogenic component decreases upwards over a 100m interval, across a fault intercept (at ~1665m burial) which might leak but does apparently not inject a distinct gas fingerprint, and towards a minimum that is associated with a sandstone sink for

microbial gas (flags b1-2). This thermogenic minimum at a microbial gas pocket reminds of the B22 constellation between 1200m and 1500m (Fig. 8–7). However, the affected interval in B24 has an overall "wet" $\Delta^{13}C2$ fingerprint which would indicate a significant advective intrusion from the thermogenic gas pool below. The fact that thermogenic wet gas components within the microbial methane dominated carrier bed are still pristine (flags b3,5,6) suggests the absence of biodegradation and that the wet gas is retained within the sandstone pore space, *i.e.* it is passively enriched. If this association of wet gas ponding with a peak microbial gas accumulation represents a static equilibrium the migration rate of thermogenic gas in this interval must be significantly slower than the rate of microbial gas generation. However, considering the implications of relatively recent thermogenic charge into the bottom segment (flag series a) it appears more likely that the overlying gas profile is at disequilibrium and therefore rather a snapshot of an ongoing thermogenic charge that is successively admixing into formerly methanogenic controlled pore fluids. Consequently, the bulged C2/C3 ratio that mediates between flag series a and b is considered as evidence of segregative migration (*e.g.* preferential adsorption of C3 *versus* C2) rather than a remnant of methanogenic ethane by-production. This assumption is supported by a similar but more faint bulge in the iC4/nC4 ratio that represents the expected smaller impact on segregative butane migration. However, these molecular effects could as well be due to the hypothesis of quasi-balanced methanogenic biodegradation that was discussed in Chapter 3.

The seismic-scale fault intercept at roughly 1550m coincides with the beginning recovery of thermogenic gas characteristics. In fact, molecular ratios between the microbial gas pocket (flag series b) and some sandier beds near the reservoir base (flag series c) are almost in 1:1 relation to the upwards increasing thermogenic gas fraction. This observation suggests that both segregative migration phenomena and *in situ* microbial gas generation must be overprinted by a much stronger effect that controls the geochemical balance between isotopic and molecular thermogenic gas fraction: the dominance of advective thermogenic gas flow through fine-grained sediments. Consequently, the differences in effective flow rates are responsible for establishment of the large-scale bulge in thermogenic gas fraction between 1480m and 1690m, with lower seepage rates through the deeper stratigraphy (flags a2 to b2) and relatively higher rates below the reservoir (flags b2 to c2). The intermediate microbial gas pocket at 1590m (flag b1) is accordingly leaking a higher thermogenic gas volume than is received from below, thereby confirms the previous assumption of a dynamic migration system, and reinforces the findings of Chapter 3 and Chapter 7 that a large fraction of microbial gas is entrapped within the pore space (dead-end pores etc.) whereas the thermogenic fraction is more prone to

utilise interconnected gas filaments for bulk flow. It is further conclusive that the rather linear legs of B24's thermogenic gas bulge represent advective flow control whereas the previously described thermogenic gas bulge that mediates between the reservoirs of B22 has a decisively convex shape which was associated with diffusive control (compare gas genetic profiles of Figs. 8–7 and 8–8).

Channel reservoir The wet gas and CO_2 isotopic signatures within the B24 channel reservoir exhibit active methanogenic biodegradation at vertically stacked gas-water contacts (GWC) that are represented by repeated decrease in C2/C3 ratio between 1350m and 1440m. These horizontal compartments as implied by the molecular ratios are in excellent agreement with both the modelled sandstone sections and high-saturation intervals (flags d-g). An overall upwards drying of the reservoired gas indicates that the identified compartments are in moderate vertical connection and that wet gas removal occurs step-wise as it passes the GWC-associated microbial community layers from channel bottom to top. In other words, contribution from lateral influx of thermogenic gas into the lower reservoir compartments is probably inferior to the advective charge through the pore space of the underlying fine-grained sediments.



Reservoir/seal interface However, the situation is different within the top reservoir compartment that overlies a seismic-scale fault zone (~1335m). Here, both isotopic and molecular thermogenic wet gas proxies (flags h2-3) indicate a local recharge with non-degraded thermogenic gas that presumably arrives via the normal fault. The absolute volume of thermogenic gas above the fault zone (flag h1) increases upwards until the gas is apparently ponding below a strong permeability contrast (flag i1). The upwards increasing wet gas biodegradation fingerprint in this interval (between flag series h and j) indicates that the fresh thermogenic fault gas is instantly biodegraded as it passes through the local GWCs and thereby driest at the top of the compartment where the ethane and methane that were spared from microbial attack accumulate. Similar to the geochemically very pronounced reservoir/seal boundary in Well B22 (see Fig. 8–7) additional influence of segregative migration on this characteristic wet gas ratio curve shape are possible, especially under consideration of a single "dry" $\Delta^{13}C2$ fingerprint in a minor ponding structure within the lower cap rock (flags k1-2). In further accordance to the previously described inversed wet gas gradient in B22's levee reservoir (Fig. 8–7) the microbial community that colonises the topmost GWC of the B24 channel must be stressed by the local fault-gas effusion rate. However, although borderline supply rates for anaerobic biodegradation suggests that the flux rate of injected (and bypassed) gas through the fault zone is very

low on a microbiological time-scale it may well pose a significant seal risk on geological time-scales, especially if fault-activity and reactivation is of episodic nature.

Top seal Apart from uncertainties in fault conductivities the roughly 70m thick thermogenic anomaly within the lower seal interval is considered a diffusion-dominated migration front rather than evidence of rapid bulk flow. Although there are few gas samples that represent the upper seal section the samples available suggest uniformly low thermogenic gas content, *i.e.* the little percolation that may take place is in equilibrium with slow methanogenic gas production and thus supports the idea of a relatively tight cap rock.

8.6 Resolving the North Alex case study

The regional setting of Wells B22 (Chapter 8.4) and B24 (Chapter 8.5) within the North Alex case study has been introduced in Chapter 1.2. Frequent occurrence of fault intercepts across both well trajectories stipulates the seismic capture of faultlines in vicinity to the North Alex mud volcano. In fact, the Upper Pliocene dip map in Figure reveals that both hydrocarbon reservoirs and mud volcano are situated amidst a complex fault zone that has an overall ENE-WSW strike line. Minor and major faults that cross the alongslope profile line between the investigated wells are marked (faults A-F).

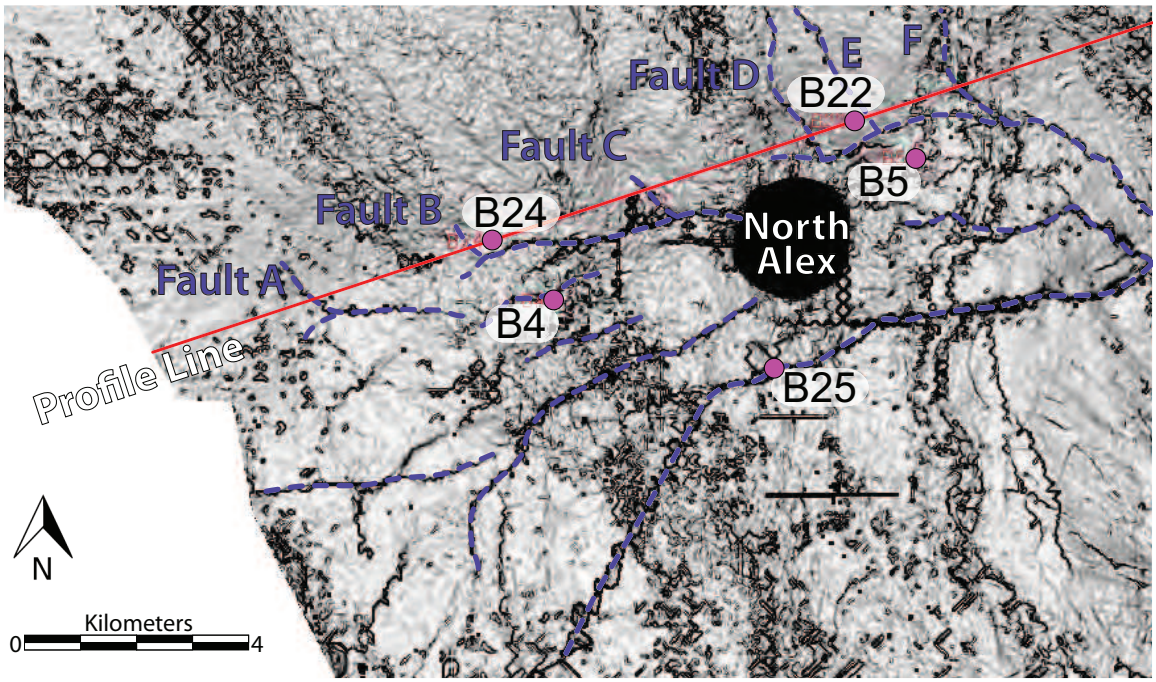

Figure 8–9 The seismic dip map of an Upper Pliocene interval of the North Alex case study suggests interrelations between mud volcano occurrence and a complex fault zone. The red profile line refers to the seismic sections in Figure 8–10.

Seismic facies interpretations have not been performed on this section but channels

and related levees are clearly visible in Figure 8–10a. Integration of the thermogenic gas fraction as a rough proxy for relative migrated gas content within the pore space affirms the impression that the local petroleum system is largely controlled by fault-associated charge and leakage (Fig. 8–10b).

In sedimentary mudstone/sandstone successions as in Nile Delta fan it is traditionally believed that fault-related hydrocarbon migration rates – both along-fault and perpendicular – are largely controlled by membrane sealing behaviour of the fault gauge matrix rather than fracture permeability because of clay mineral entrainment along the shear planes (Schowalter 1979, Eichhubl *et al.* 2005). Migration control by fracture or joint permeabilities is usually focussed "at locations of structural complexity such as fault intersections, extensional steps, and fault-segment terminations" if episodic reactivation of shear planes hampers a complete plugging with diagenetic cement (Eichhubl *et al.* 2009). Consequently, capillary entry pressure is considered the most important parameter for membrane fault seal studies (Manzocchi *et al.* 2011). Juxtaposition of sandy *versus* clay-rich sedimentary units may foster changes from structurally- to stratigraphically-controlled migration (*e.g.* Duchesne *et al.* 2011) depending on whether the least resistant entry pressure is exerted from either fault-gauge or adjacent stratigraphy. Sealing and non-sealing faults may coexist dependent on the burial history of a basin (Barr 2007). In case of the North Alex case study it must be noted that the assigned preferential fluid flow routes in Figure 8–10b are subject to the condition that across-fault migration is inferior to migration along the down-dip side of seismic-scale fault planes.

Further, it was discussed in Chapter 6 that the formation of free gas filaments from progressive exsolution of an internal gas source such as methanogenesis would be inhibited without microfracture propagation (Gardiner *et al.* 2003, Algar & Boudreau 2010). Although it was argued that the low present-day overpressures in the relatively shallow Nile Delta Pliocene explicitly preclude micro-fracturing it must be considered that shear zone displacements within the vicinity of a normal fault plane may well establish and maintain bulk flow networks by *in situ* exsolution of microbial methane.

Restricted across-fault migration enables the charge of the B24 channel reservoir via its associated levee (Fault A in Fig. 8–10b) and at the same time explains the entrapment of a minor gas pocket at the opposite side of the fault plane (between 2750ms and 3000ms). At the same time, it relativises the formerly leakage-allocated nutrient shortage of the B22 biodegrading community by the additional information that re-charge from its adjacent channel reservoir is hampered by fault F. It is suggested that across-plane sealing is particularly strong in terms of faults A and E-F whereas the detailed well analysis of B24 has implied that advective flow does occur across faults B and C. The latter is affirmed

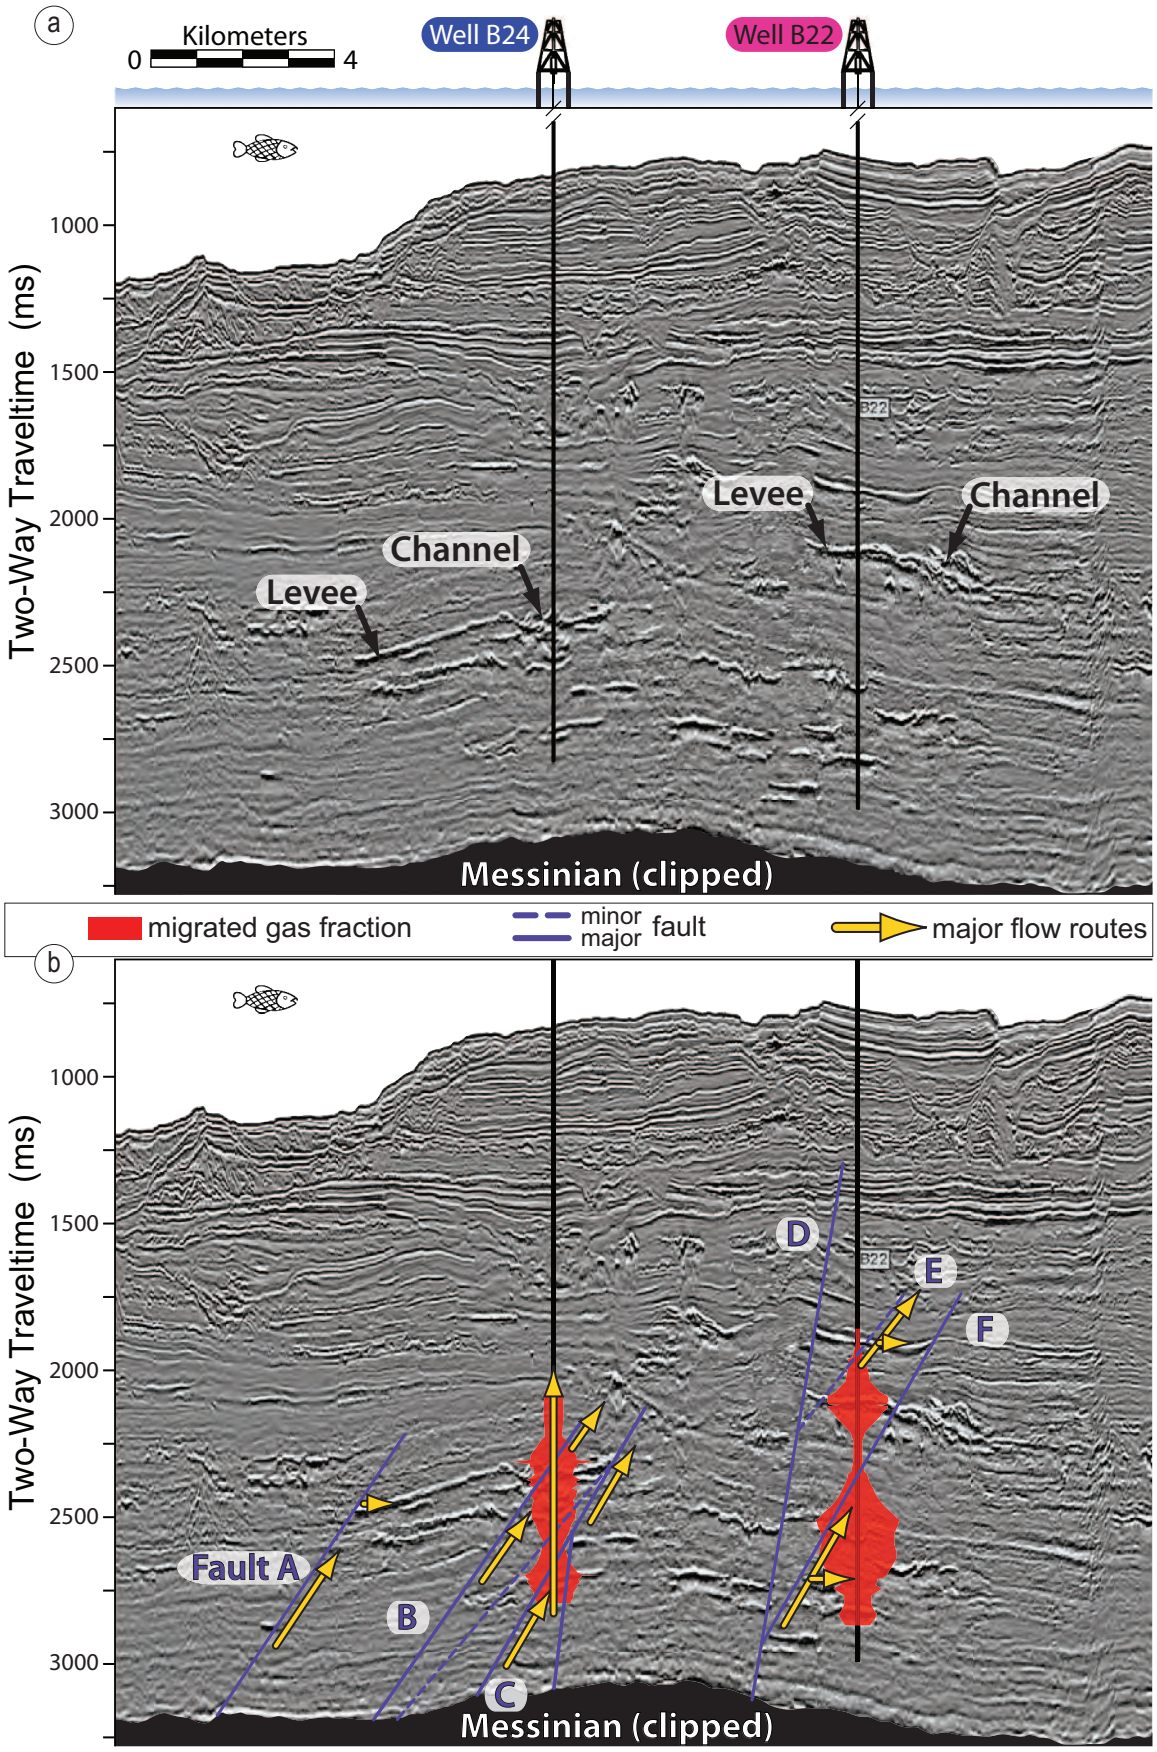

Figure 8–10 Along-slope seismic profile through the North Alex case study (see profile line in Fig. 8–9). (a) Raw cross-section indicates position of the B24 channel reservoir and B22 levee reservoir. (b) A succession of stacked normal faults is intersected by a steep fault (fault D) that may have a significant strike-slip component (Twiss & Moores 1992). The B22 gas profile is mostly fault-controlled whereas the more balanced migrated (thermogenic) gas fraction along B24 implies a significant contribution of the pore network in the mudstone non-reservoir.

by a more balanced distribution of migrated gas along the B24 trajectory as opposed to strong contrasts in B22 (see red fields in Fig. 8–10b). However, direct evidence for the role of North Alex mud volcano and the possibly related steep fault D cannot be resolved with the available data basis.

Relevant events within the North Alex case study are schematically summarised in Chapter 9.

Chapter 9 Migration in the deep biosphere – a discussion

It has been demonstrated that thermogenic gas is exposed to a large variety of secondary alteration phenomena during its passage through the methanogenic zone of the Nile Delta's deep biosphere.

Migration mechanisms and pathways There is multiple evidence in the literature that hydrocarbon degrading microbial communities do not have direct access to nutrients in a free gas phase, be it in terms of aerobic oxidation of methane in temperate soils (Tyler *et al.* 1994), aerobic oxidation of hydrocarbons in shallow marine sediments (Grant & Whiticar 2002), or anaerobic biodegradation within commercial petroleum accumulations (*e.g.* Jones *et al.* 2008). The metabolic requirement of dissolved gaseous species is also known for some higher plants (*e.g.* Chanton *et al.* 1992). Such incompatibility between a free gas phase and microbial metabolism enables a discrimination between the two fundamental transport mechanisms of hydrocarbon migration: diffusion and advection. Since diffusive transport rates are up to two orders of magnitude lower than advective flow across an interconnected hydrocarbon phase (England & MacKenzie 1989, England 1990) the identification of non-degraded and non-diffused gas samples with an advective mixing trend between arriving thermogenic and *in situ* microbial gas is an invaluable proxy to track stratigraphic units that harbour a sufficient micro-saturation for advective seepage.

The comparatively rare occurrence of clearly diffusive fingerprints in the combined gas data of the Nile Delta is perhaps surprising given that the majority of samples is taken from clay-dominated stratigraphy. Moreover, a continuous "dry" mixing trend that may be associated with diffusive/microbial control on gas migration rates is almost exclusive to a single well section (B22). Considering the discussed drag in isotopic response to microbial gas generation and consumption (Chapter 3.4) it is therefore likely that the diffusive signal is only detectable if the thermogenic end-member has compositionally adjusted to dry microbial gas through wet gas biodegradation. Although no ethane solubility calculations have been conducted in this work – because the overall low C2 volumes could not be modelled with the required accuracy – the most likely explanation for this behaviour is that the bulk C2 of the "dry" trend is in aqueous solution and thereby fully accessible to microbially-mediated overprints. In this scenario, comparably high dissolved methane concentrations (Chapter 7.3) do not have a diminishing effect on C2 solubility because dissolved low-molecular weight hydrocarbons act as "ideal solutions" due to their overall low solubilities in water/brine (de Hemptinne *et al.* 1998b, Dhima *et al.* 1998 & 1999).

Although direct field evidence for filamentary advective flow pathways on the pore scale could not be resolved by the saturation model (Part III) indirect support for their existence is given by the gas genetic distribution along the investigated boreholes. As thermogenic gas fingerprints represent the minimum fraction of migrated hydrocarbons the identified thermogenic anomalies above accumulations witness the percolation progress. Likewise, widely observed thermogenic anomalies below overlying gas pockets represent back-filled migrated gas that is retained within the filamentary flow network by the upwards increasing pressure communication with the accumulated free gas column (Fig. 9–1). If cap rock-bypass systems (CBS) such as conductive fault zones or sandstone intrusions are absent both percolation front and backfilled gas may eventually meet to provide a filamentary pore-scale flow network that maintains a dynamic charge/leak scenario for the accumulations involved, *i.e.* hydrocarbon loss is a function of reservoir charge rate and relative permeability of the cap rock such as proposed for the Well B19 trajectory. Omnipresence of retained methanogenic and – at greater depth – palaeo-methanogenic gas will enhance this process because (1) an already methane-saturated formation water buffers the diffusive loss of the migrating/ponding thermogenic gas and (2) exsolved bubbles of microbial methane will speed-up percolation processes as the net distance that needs to be bridged by capillary injection thereby decreases.

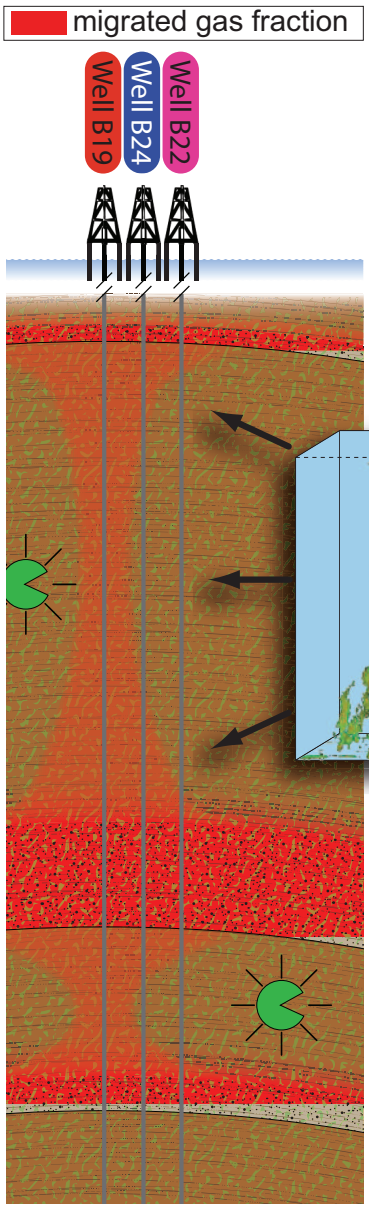

Figure 9–1 The relative extent to which pore-scale flow pathways are activated is roughly proportional to the sampled thermogenic gas fraction under the assumption that methanogenic gas production is pervasive in the mudrock non-reservoir. Such a migration proxy is not valid for Well B20 because its formerly thermogenic reservoir gas is almost completely lost through the cap rock. See Figure 8–1 for pictogram legend and Figure 7–24 for details about the cubic inlet.

Naturally, migration through the pore space becomes second choice if conductive fault zones are crossing the seepage pathway. In the North Alex case study apparent fault (re-)activation in conjuction with mud volcano activity is an excellent example for largely fault-controlled reservoir charge and leakage (Fig. 9–2). Migration along the down-dip side of sealing fault planes would be enhanced by progressive exsolution of microbial gasses upon seismic microfrac-

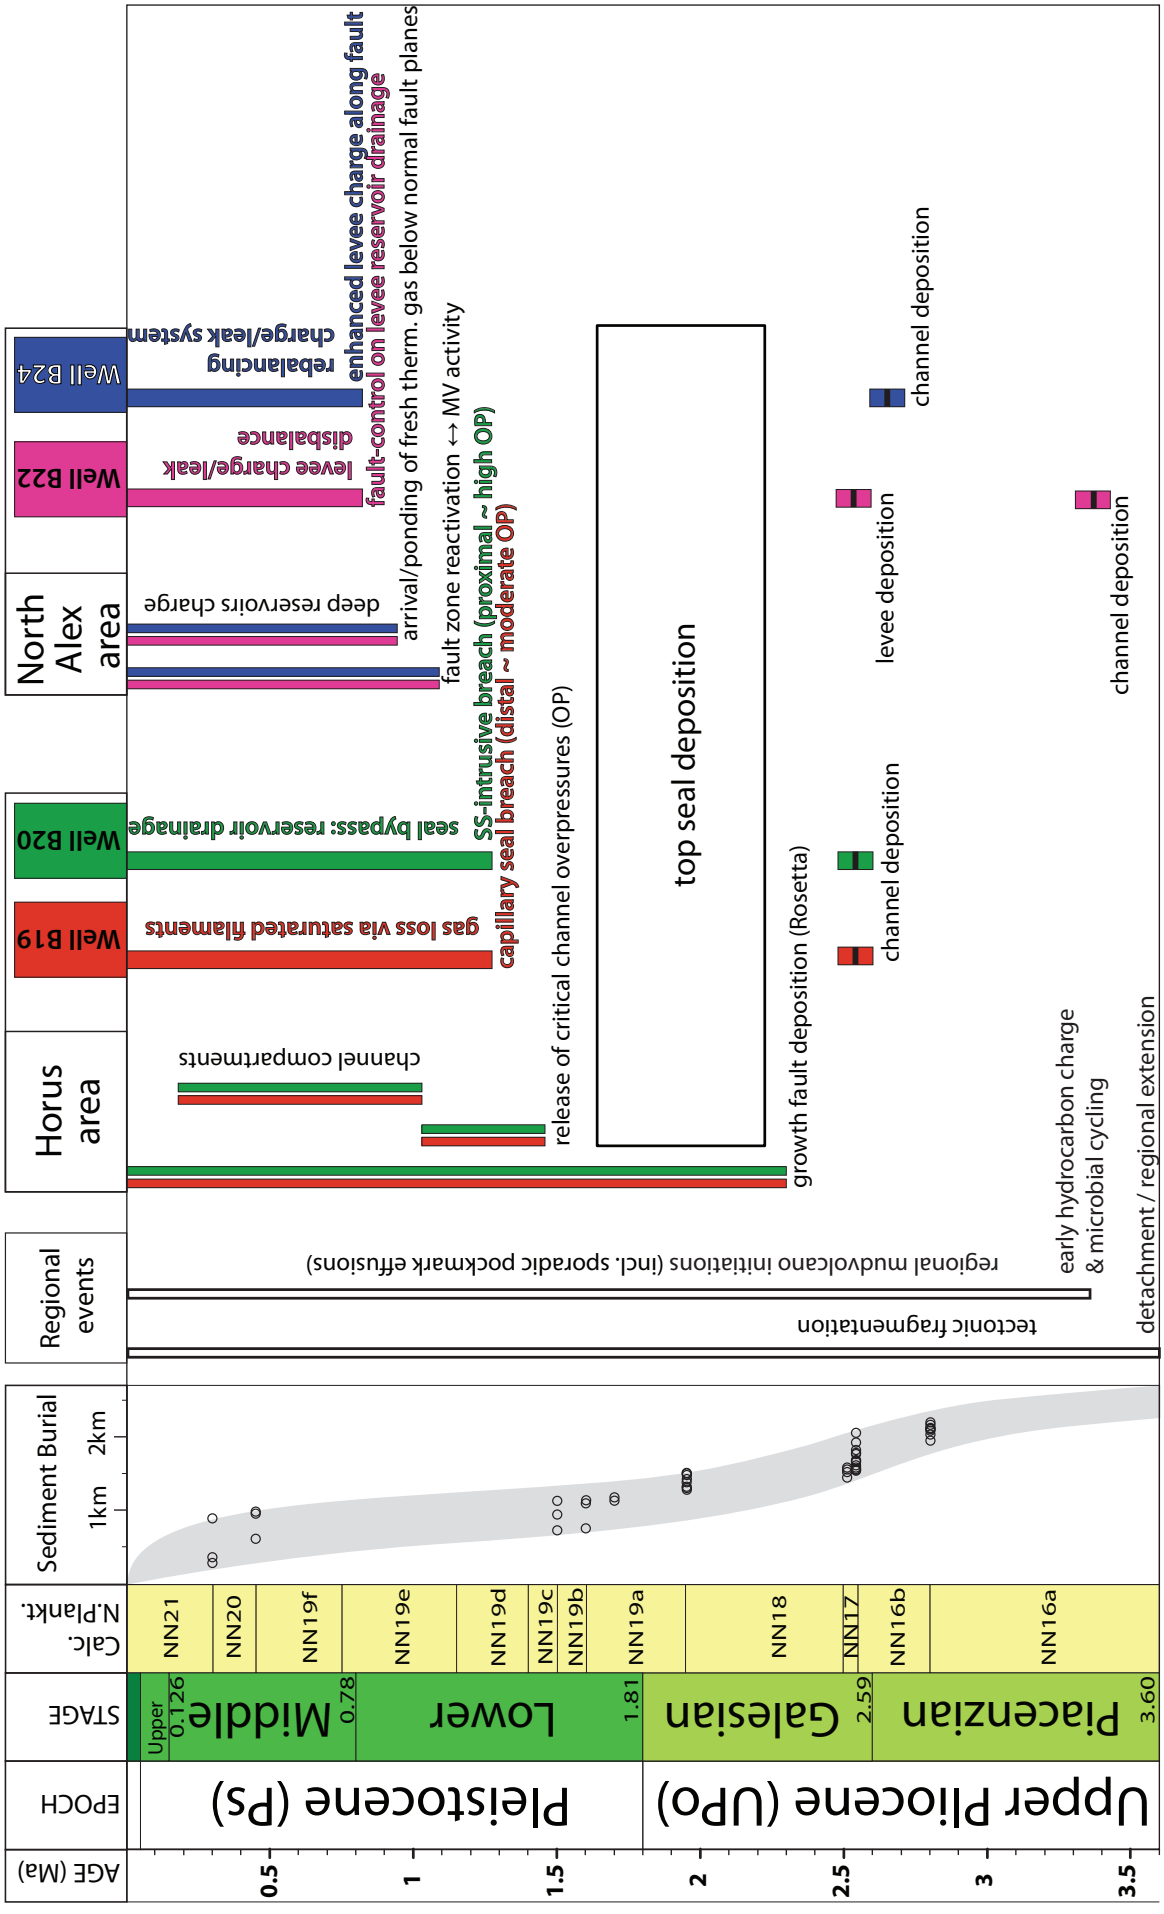

Figure 9–2 Schematic geological timeframe of the events in the Horus and North Alex case study. This figure summarises the interpretations from Chapter 8.

ture propagation (Gardiner *et al.* 2003, Algar & Boudreau 2010). In the tectonically less fragmented Horus area growth fault-induced palaeo-overpressures that were regulated by early conductive and late sealing fault properties are held responsible for the early capillary breach of the B19 seal interval and late pressure compartmentalisation that eventually lead to the palaeo-drainage of the B20 channel leg through core-scale sandstone intrusions (Fig. 9–2).

Implications for the deep biosphere It is standing to reason that remnant microbial communities that comprise both biodegrading bacteria and methanogenic archaea happened to colonise initially empty reservoir structures early at shallow burial and flourished upon the eventual establishment of reliable charge routes (*e.g.* Wilhelms *et al.* 2001a). The idea that the timespan between early colonisation and late (deep) hydrocarbon charge is bridged by a long period of microbial dormancy appears incomprehensive from a biological perspective because a late reactivation would have spared the necessary adaptation of the affected microbial strains to the environmental changes that occur during burial through the deep biosphere (see Fig. 2–3). Instead, vital and active microbial communities at depth are expected to have evolved more or less continuously during their burial history.

Further, results from the gas saturation model in Chapter 7 indicate the pervasive presence of so-called gas-water contacts (GWC) both within thin beds and mudrocks of the non-reservoir. It therefore appears increasingly unlikely that biodegrading bacteria are exclusive to GWCs of commercially-sized hydrocarbon accumulations but must have branched off and specialised from remnant strains that were capable of various different metabolic pathways. The well-documented traditional association of biodegradation with large-scale accumulations must be considered as a skewed observation because here it is only most easily recognised by the large-scale wet gas molecular and isotopic gradients that spread across accumulated petroleum columns as a diffusive/density-driven response to microbial cracking at its base. Such commonly acknowledged pattern that was shown to cross the B22 levee reservoir base (Chapter 8.4) gives rise to the assertion that microbial communities within the deep biosphere are capable to respond to nutrient shortage by physical relocation towards alternative supply routes.

As there is no evidence of anaerobic oxidation of methane (AOM) the overall very dry gas composition within the Nile Delta sediments poses an ideal case study for the detection of hydrocarbon trace metabolites from vital wet gas-fermenting bacterial strains within the non-reservoir. It has been shown by the bulk analysis of the provided gas data (Chapter 3) that wet gases tend to balance at certain molecular ratios as a rough function

of temperature regime – particularly if relatively high concentrations are involved (Figs. 3–9 and 3–10). Since isotopically light traces of ethane and propane are a by-product of methanogenesis (see Chapter 2.2) it appears comprehensible that a supposedly weak contemporary biodegradation activity is not recognised in the net carbon isotope signature because of counterbalancing isotope shifts (microbial production *versus* preferential consumption of light $\delta^{13}C2$). The discovery of such mutually annihilating isotope shifts is further hampered by the general drag in isotopic response to both methanogenic admixture and biodegradation as opposed to their instantaneous response in molecular wet gas depletion (Fig. 3–11). Nevertheless, molecular effects of isotopically balanced methanogenic biodegradation in the non-reservoir remain equivocal due to a similar magnitude of segregative wet gas removal and must be carefully discriminated in the context of associated borehole gas profiles (Chapter 8).

The recognition of microbial alteration effects on hydrocarbon isotopes and composition is vital to a correct interpretation of the migration and entrapment history of sampled gases in this area, not least because unrecognised microbial control on ethane carbon isotope ratios may lead to severe miscalculations of thermogenic gas maturities. For instance, an absolute $\delta^{13}C2$ variation of ~10 ‰ across only a 100m interval below the B22 levee reservoir (see $\Delta^{13}C2$ in Fig. 8–7) exceeds the entire maturity range of the Berner & Faber (1996; Fig. 3–5) isotope model and could thereby lead to the false perception of mixing thermogenic gases. Instead, it was demonstrated in this study that the actual gas maturity range across the entire case study is very confined due to low variations in fermentation-resistant isobutane carbon isotope ratios (Chapter 3).

Chapter 10 Conclusions

The Plio-/Pleistocene stratigraphy of the western Nile Delta fan is an example environment for the admixture of relatively dry thermogenic gases (>98% methane) into even drier *in situ* microbial gas (~99.9995% methane). Biodegradation processes within the deep biosphere are responsible for methane-dominance even in sections with high thermogenic gas fingerprint. The lack of hydrocarbons other than methane hampers the identification of wet gas ponding structures. Also, mixing and degradation processes are sufficiently pervasive to conceal the supposedly narrow gas maturity range.

However, trace concentrations of wet gas in such microbial environments foster the analysis of metabolic processes that accompany methanogenesis but would be concealed if large quantities of less mature hydrocarbons such as oils were present. It has been shown that ~2 vol.% of thermogenic ethane suffice to conceal its microbial isotope shifts as opposed to trace ethane concentrations in biodegraded/methanogenic diluted thermogenic gases.

Also, a methane dominated environment allows the approximation of methane content by total gas concentration logs that were monitored during drilling. Otherwise the presented saturation model would not be applicable to overall "wetter" or even oil-prone petroleum systems. However, gas saturations as modelled from wireline logs do not resolve the presumable patchy/filamentary micro-conduits of free gas phase that would allow bulk flow as opposed to relatively slow molecular diffusion upon capillary entrapment. Nevertheless, gas geochemical analyses imply that leakage through the mudrock pore space poses a high seal risk particularly if hydrocarbon buoyancy pressures were at any point in the past sufficient to overcome the capillary entry pressure of the sealing unit and thereby paved the filamentary saturation pathways for permanent bulk flow. *In situ* generation of microbial methane may play a vital role in sustaining the interconnectivity of leaking hydrocarbon phases both within mudstone cap rocks and along conductive fault zones.

All these processes take place in a lithological environment that many geologists before have struggled to capture in a quantitative and reproducible manner at both core scale and sample resolution. Using core image pattern recognition in conjunction with the herein conducted image-to-grain size integration may well pose a fruitful approach for future researchers to strip-off ambiguity from descriptive interpretations of sedimentary facies.

Finally, the integrated study of both fluid volumetrics and geochemical borehole pro-

files resolved the hydrocarbon migration history of selected Nile Delta focus areas in the context of lithology, stratigraphy, and regional basin architecture. It was confirmed that hydrocarbon loss through the pore space becomes second choice if the local petroleum system is controlled by fault activity. The question whether the latter is a common feeding mechanism for seafloor pockmarks remains unresolved owing to the available data basis. Further, presence of subseismic-scale sandstone intrusions across the cap rock of an underfilled channel reservoir implies that the capillary breach of the same top seal above an adjacent and filled channel compartment was initiated by substantial palaeo-overpressures.

Chapter 11 Applications and outlook

This chapter is designed to emphasise potential industrial applications and state recommendations for future research in the different aspects of this work.

Part I: Geochemical gas mixing model The applied gas mixing model represents a generic approach to determine the migration processes of mixed thermogenic/biodegraded/microbial gases in the subsurface. Successful transfer to other localities depends on the following prerequisites:

- Low variations in thermogenic gas maturities and presence of both methanogens and biodegrading microbes (methanogen window of deep biosphere)
- Good knowledge of thermogenic/microbial gas endmember chemistry from measured data
- High methane content (ideally >95%) in thermogenic gas to emphasise ethane isotopic shifts during mixing with its microbial counterpart (>99.9995% methane)

Further, the role of adsorption related isotope fractionation must be carefully quantified in future laboratory studies. It was outlined in Chapters 2.3 and 3.1 that adsorped (HSG) methane is in general isotopically heavier compared to interstitial gases. This circumstance could imply either preferential adsorption of thermogenic gas (*e.g.* Whiticar 2002) or severe ^{13}C fractionation of purely microbial gas (*e.g.* Friedrich & Jüntgen 1972), each with fundamentally different implications for the nature of gas migration through the subsurface.

Part II: Upscaling of lithology The calibration of petrophysical wireline log signals through the proposed upscaling procedure (core samples → core images → wireline log interval) poses a promising approach for software supported applications in the petroleum industry. Although the procedure is not of generic nature the definition of conversion functions between the required input data (rock sample analyses, core images, log signals) from new boreholes can easily be automated with basic software programming knowledge.

In terms of lithofacies reproducibility the following key issues must be addressed in future research:

- more sand-prone core sample coverage will improve the grain size model quality
- automated core image texture recognition
    - improves allocation of both lithofacies boundaries and borderline lithologies

- allows more objective parameter studies on interrelations between lithology/texture and wireline log signals
- improves the reproducibility of (supervised) ANN-supported wireline facies recognition

- unsupervised ANN training
  - automated wireline facies recognition that is solely based on the given suite of log signals will inevitably show the highest possible reproducibility
  - output (wireline) facies must be examined for textural/lithological (core image) features that are sufficiently characteristic to provide a unique set of lithofacies

Part III: Hydrocarbon saturation Transferability of the proposed saturation model to other boreholes/case studies is subject to a precise calibration of wireline log signals (total porosity, clay content, neutron/electron density). As there are hardly any absolute signals in petroleum engineering it is recommended to implement the proposed saturation model along with the same software tool that allows the above upscaling & signal calibration procedure (core samples → core images → wireline log interval).

In case studies were methane is the dominant hydrocarbon species and carbonates are mostly absent the commercial benefit of the applied technique is as follows:

- improved estimates of total gas in place volumetrics (*e.g.* shale gas reservoirs)
- saturation logs may serve as calibration reference for basin-wide fluid flow models

In terms of further research, the general lack of direct saturation reference data other than model derived estimates will necessitate the conduction of laboratory experiments similar to the work of Archie (1942). Laboratory tests on the interrelation between neutron/electron density and hydrogen content – in a porous medium at different hydrocarbon saturations – will provide the only reliable information about the quality of the herein applied saturation model.

Depth synchronisation Finally, it has been demonstrated that signal depth matching of cores/mudlog to the wireline log reference is crucial for an integrated calibration of these different wellsite data acquisition techniques. Both grain size model (Part II) and saturation model (Part III) are suited for high-precision depth matching (Appendix B) and provide a promising reference data set for non-linear shifting algorithms. Naturally, limitations are given by the lowest depth resolution of the involved data profiles.

Appendices

Appendix A: Depth Synchronisation

This chapter deals with the restoration of depth coherency between the different data types used for the integrated assessment of hydrocarbon migration in the case study. The difficulties and limitations involved are outlined in Chapter 1.3.

A.1 Core Shift

There are basically two methods for matching the driller's or core depth to the logger's depth: adjustment of core gamma ray (COGR) to conventional gamma ray (HSGR), and adjustment of core images (CI) to microresistivity borehole images (OBMI). The accuracy of both methods depends on the lithological and pore fluid contrast, respectively. Intervals with high resistivity contrasts, *e.g.* gas-filled sandstones interbedded with mudstones and carbonate bands within mudstone sections, can easily be fitted using the image data. Muddy sections with dominantly brine-filled sandstone interbeds and laminae are better suited for COGR-HSGR fitting.

However, a variety of problems may occur that influence the accuracy of the shift:

- OBMI: flap/pad mismatch of the OBMI tool, wash-outs and hole rugosity, lowered pad response in high resistivity gas sands, diagonal striping due to damaged borehole wall
- CI: preserved samples have not been photographed (30 out of 100 cm per image), damage to the core due to cutting
- HSGR: bulk intensity shift at the casing-to-open hole boundary
- COGR: alternating intensities between intervals due to different time-steps of measurement, depth inversions from inversed scans

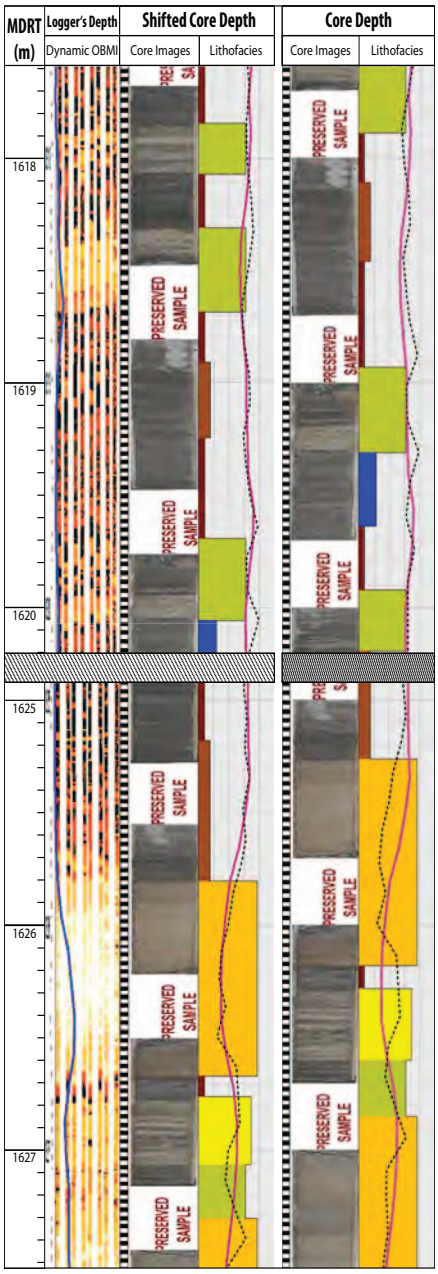

Figure A–1 Example intervals from Well B19 showing shifted and unshifted cores. Deep resistivity log (blue line), HSGR (red line), COGR (black dashed line), for facies see Fig. 5–3.

Methodology integration Ideally, CI-to-OBMI and COGR-to-HSGR fitting should end up with comparable results for the most likely core position along the logger's depth. However, application of the CI-shift to the COGR logs resulted in quite uniform COGR-to-HSGR offsets (see below). Investigation of the CI-to-COGR depth integrity revealed that some core sections have either a positive or negative vertical offset towards their associated COGR logs, *i.e.* either smaller or larger depth were recorded for both first (top) and last (bottom) measurement.

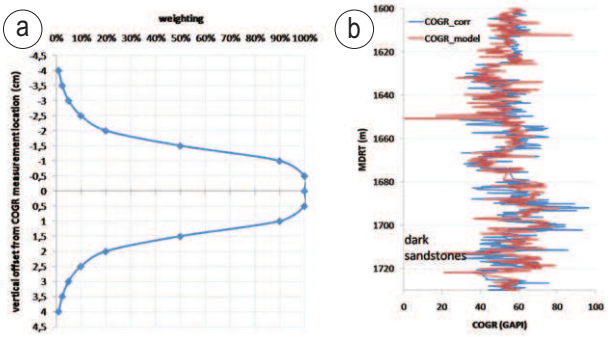

Figure A–2 (a) Scale modulation of CI parameters to match the cummulative gamma ray reception at the device's crystal. (b) Inaccurate COGR model output from modulated CI parameters.

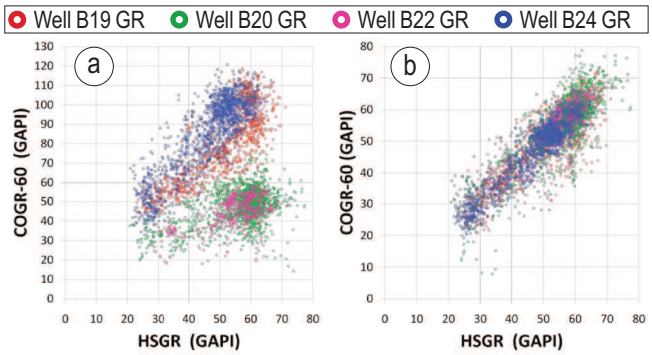

Figure A–3 (a) Raw and (b) calibrated COGR signal intensiity via linear referencing of the the 60cm geometric mean of each shifted COGR-interval to the conventional wireline log signal (HSGR).

As indicated in Chapter 5.2, long attempts to couple the CIGS model to core gamma ray (COGR) response did not return satisfying results. Although the scale and resolution discrepancy between CIs and COGR response was considered (Figure A–2a) various empirical calculations from CI parameters did not return an accurate model of the COGR response (Figure A–2b). These inconsistencies were attributed to (1) a too loose cause-and-effect relationship between CI parameters and COGR, (2) uncertainties in COGR device settings (sensibility; Fig. A–3), and (3) mismatches in CI an COGR depth at the required resolution (~1cm). However, although not applicable for

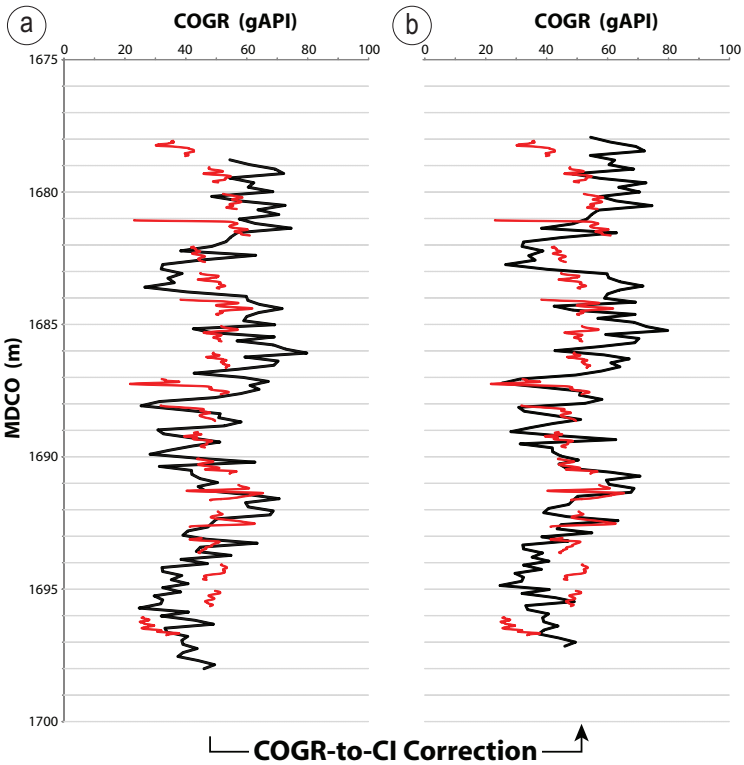

Figure A–4 Example core section from Well B19 showing measured (black) and core image-derived (red) gamma radiation (a) prior and (b) after COGR bulk shift.

high resolution purposes the best-fit models provide at least partly characteristic reference logs for COGR-to-CI depth correction assuming a simple bulk shift of the COGR logs (Fig. A–4).

In the end, the best agreement between matching all these data has been converted into a progressively linear shift of the core depth to the actual logger's depth (Fig. A–5).

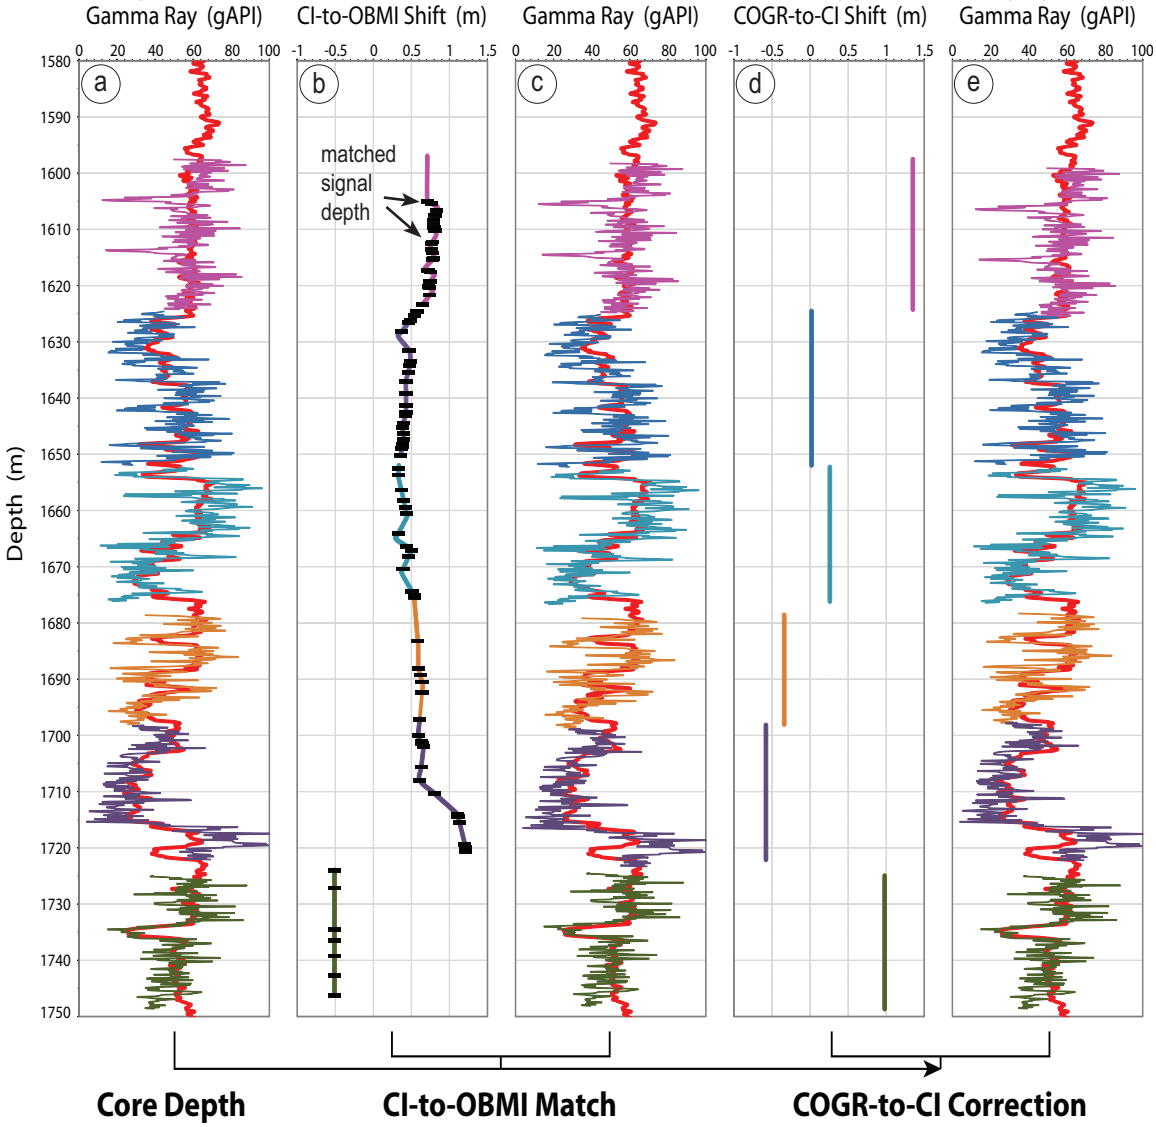

Figure A–5 (a) Natural gamma radiation from wireline log (HSGR; red) should be matched by core gamma ray (COGR; one colour per section) if the core is shifted into the correct logger's depth. However, (b) the shift of core images (CI) relative to borehole micro-resistivity images (OBMI) resulted in (c) minor mismatches between HSGR and COGR. (d) Matching the measured COGR log to the CI-modelled values (e) led to an improved COGR-to-HSGR relation (*e.g.* at 1720m). Example from Well B19.

A.2 Gas Shift

The wellsite gas logs from the mudlogging process were successfully shifted using a rather probabilistic matching to the total gas (TG) model from wireline log porosities (Chapter 7.1). Peak-matching between distorted measured molar gas concentrations and modelled logs was performed for the most probable matching pairs with the final mudlog shift resulting from linear interpolation in between (Figs. A–6 to A–9).

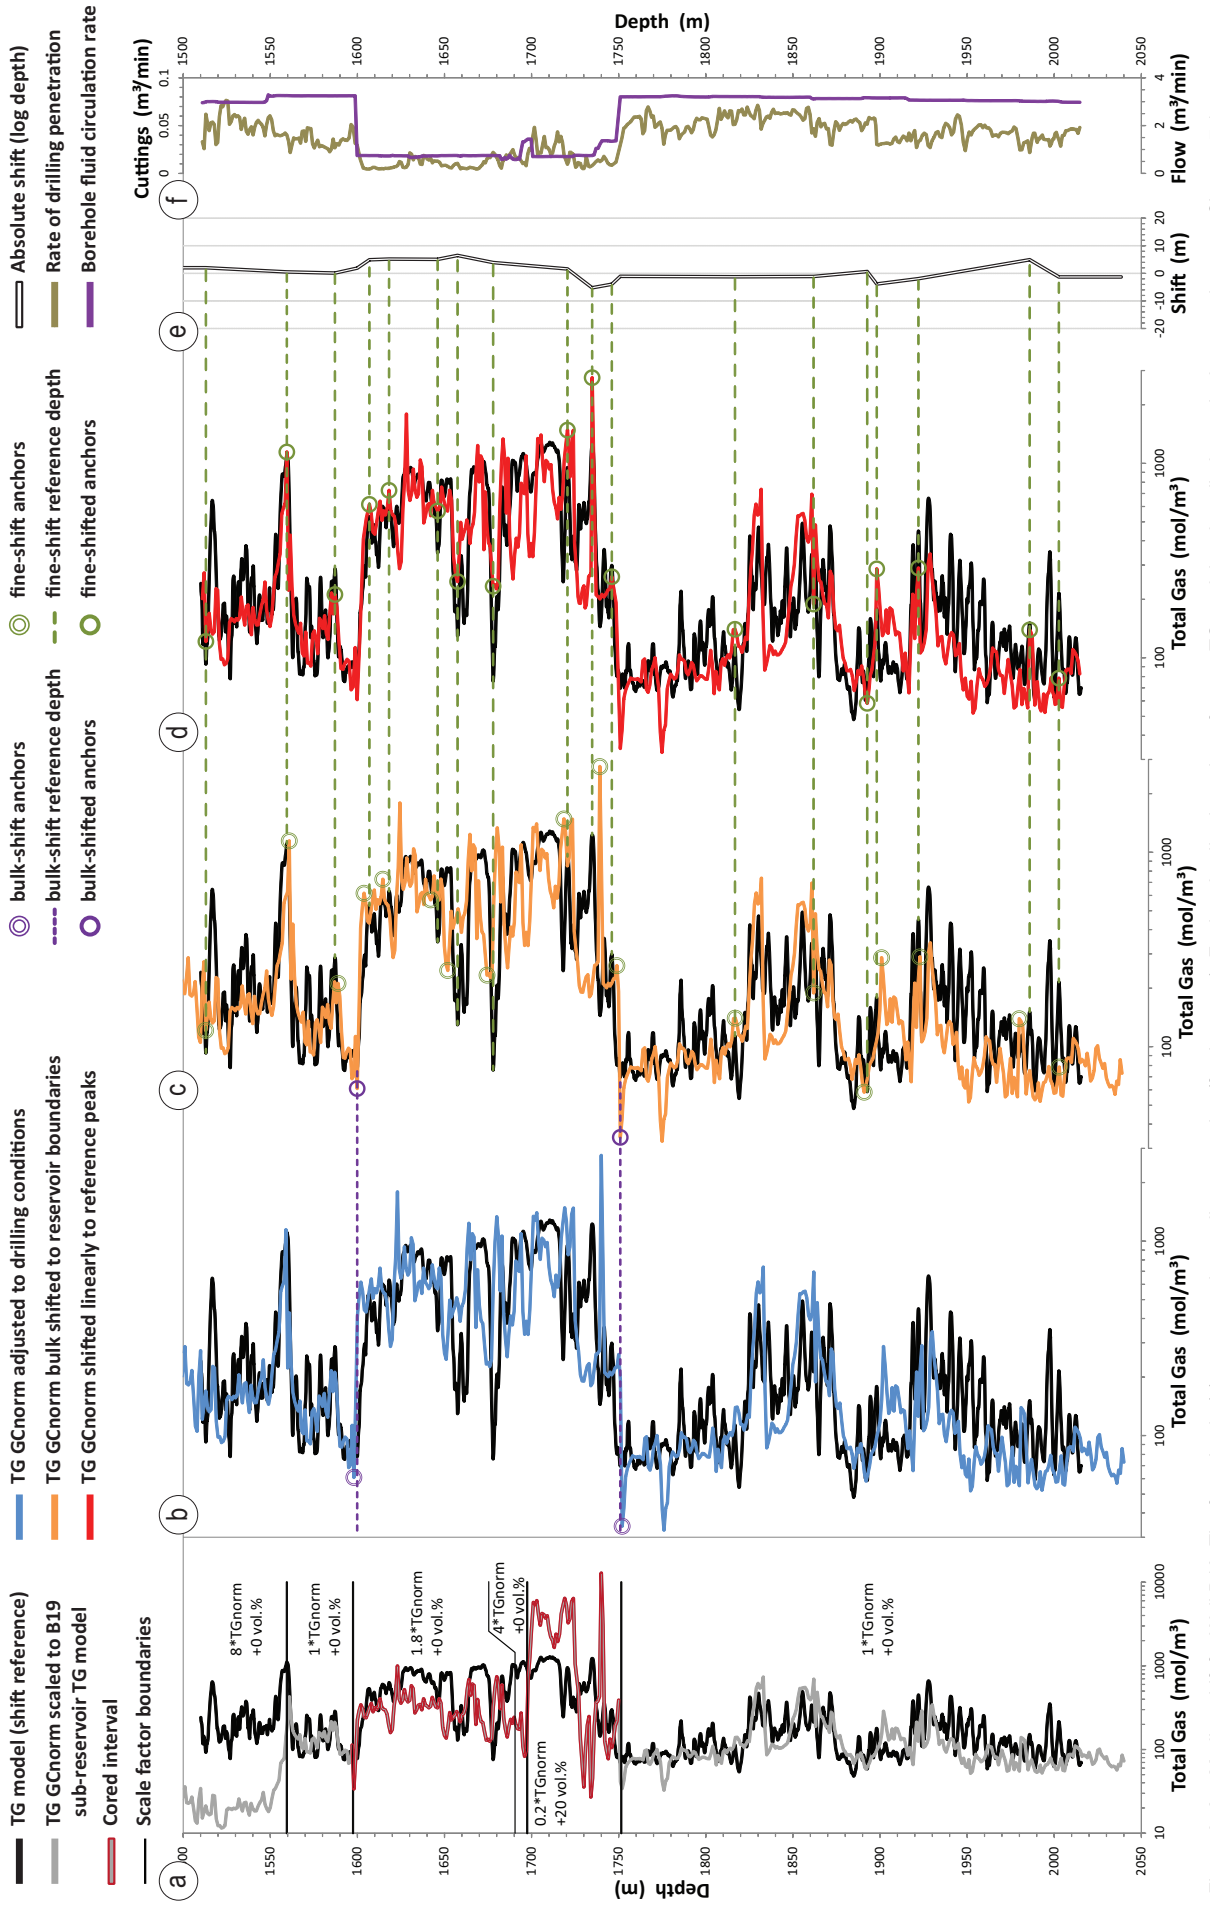

Figure A–6 Mudlog shift for Well B19. The formulae in (a) represent the mudlog correction (f_x + intercept). Further details about the reference TG model and applied magnitude corrections see Chapter 7.1.

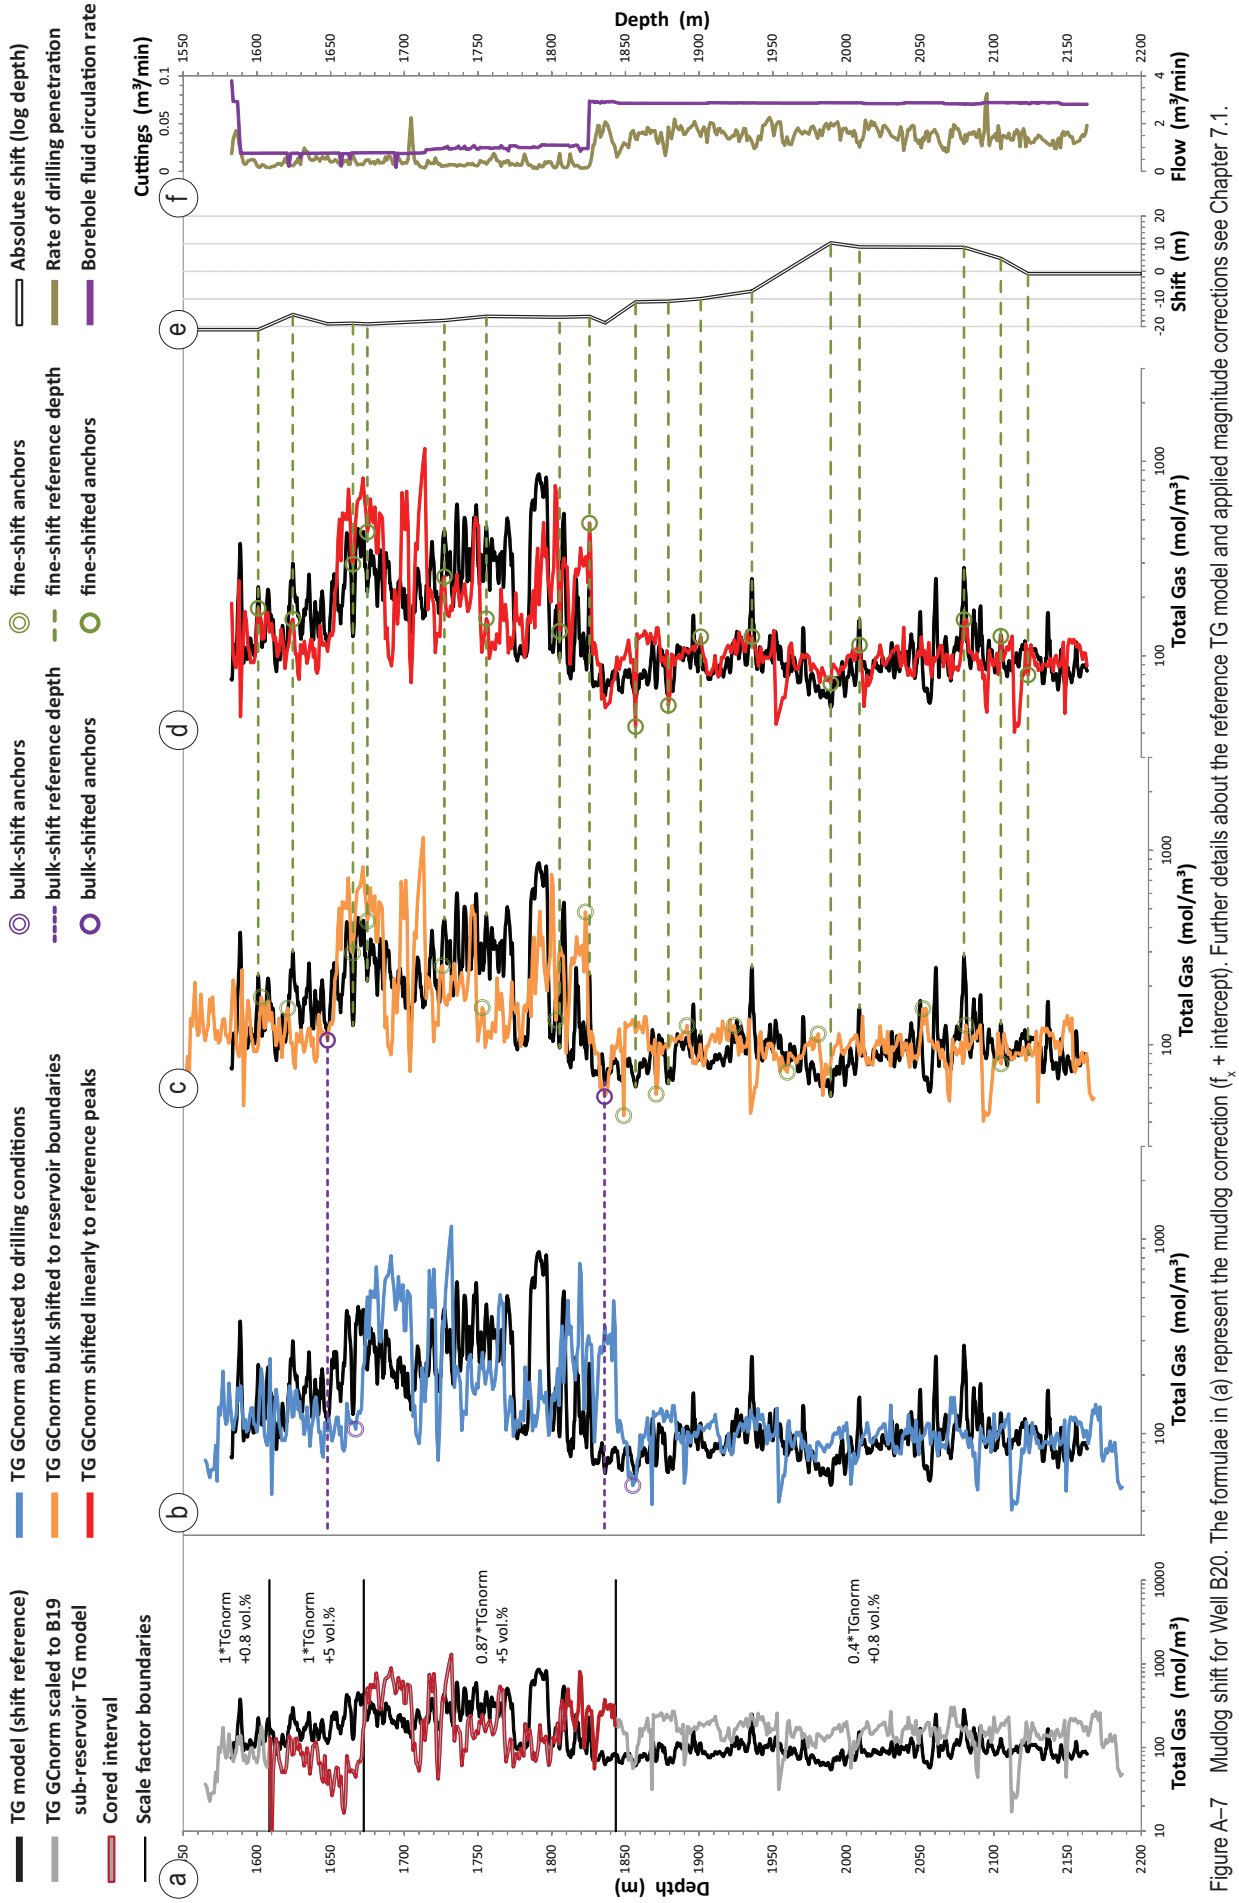

Figure A–7 Mudlog shift for Well B20. The formulae in (a) represent the mudlog correction (f_x + intercept). Further details about the reference TG model and applied magnitude corrections see Chapter 7.1.

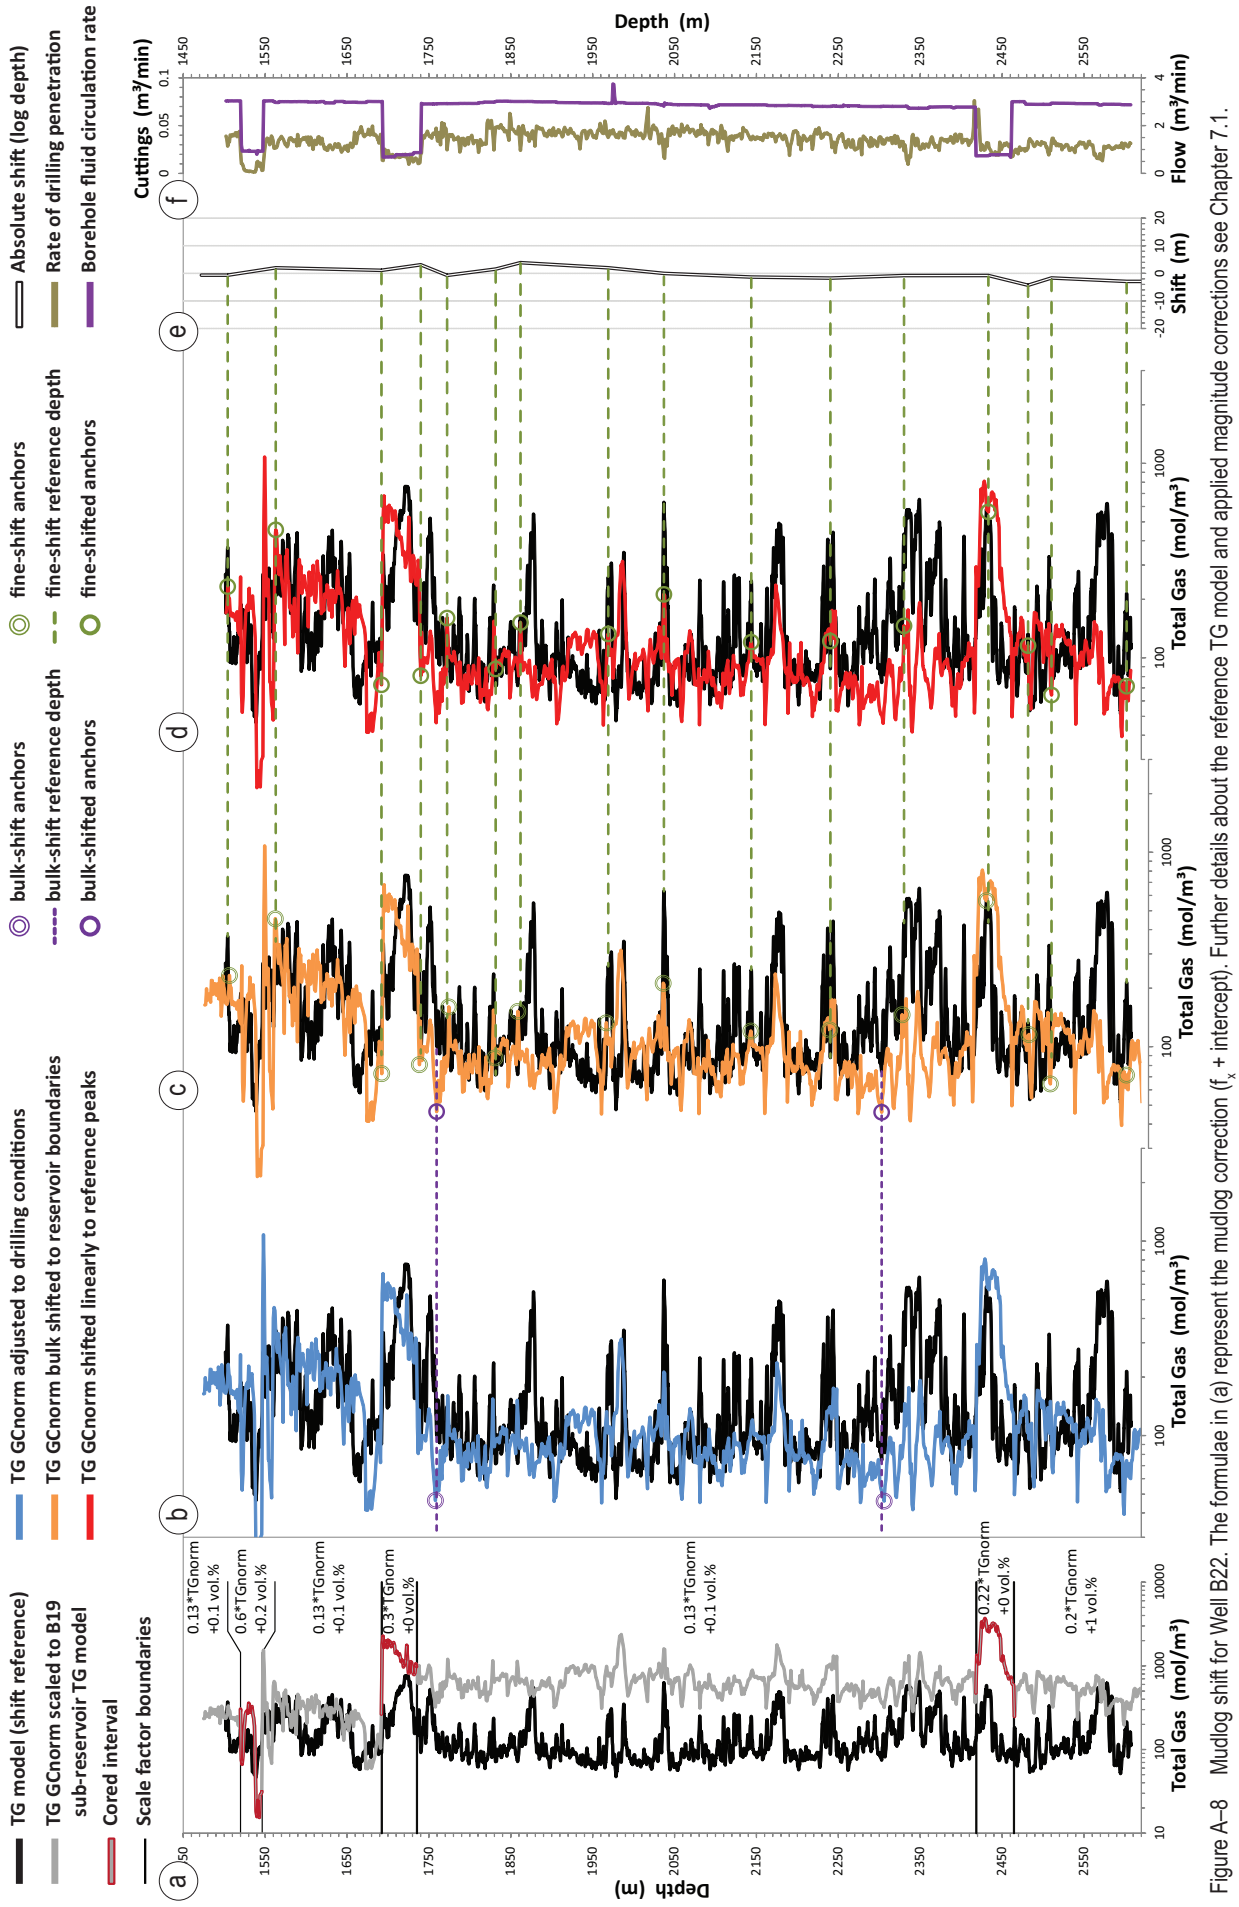

Figure A–8 Mudlog shift for Well B22. The formulae in (a) represent the mudlog correction (f_x + intercept). Further details about the reference TG model and applied magnitude corrections see Chapter 7.1.

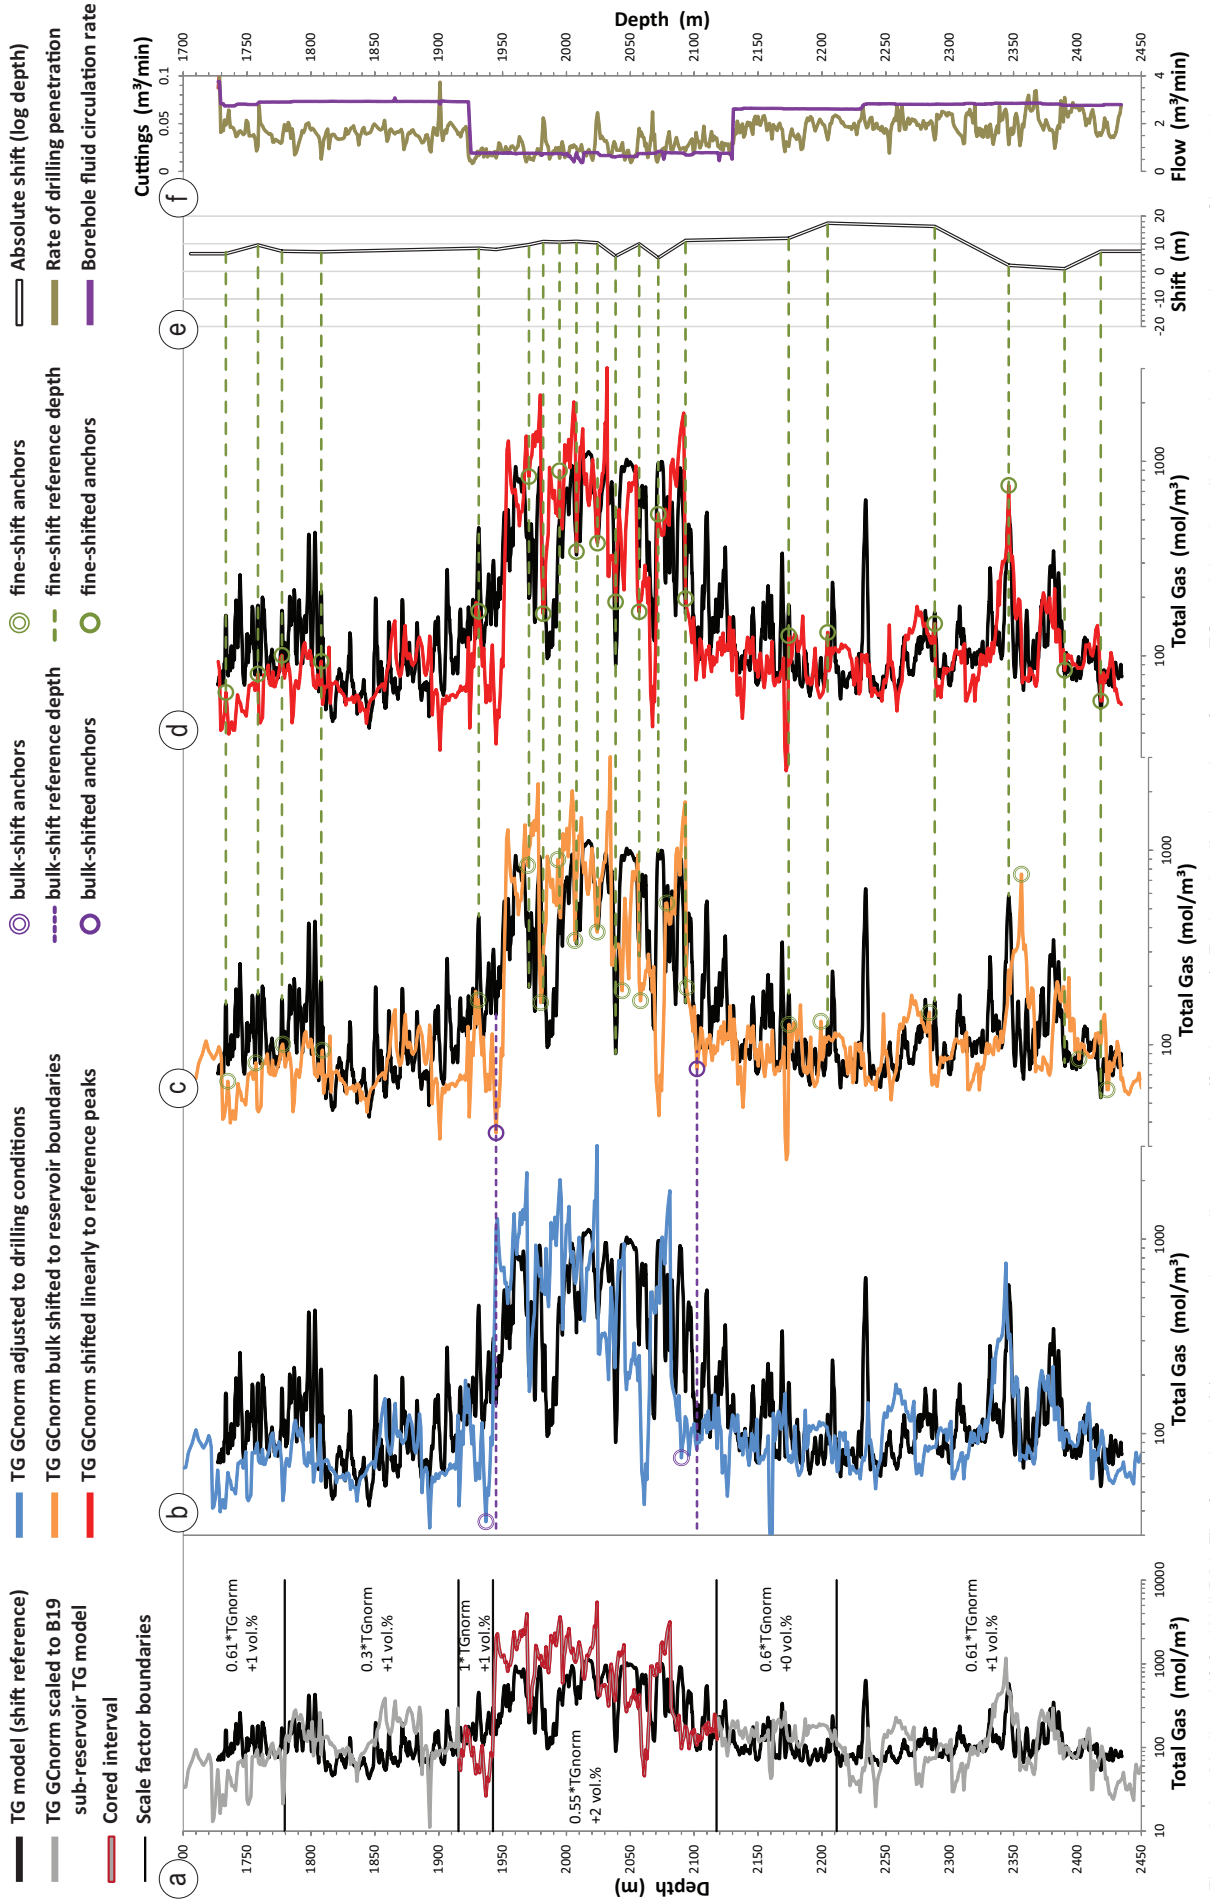

Figure A–9 Mudlog shift for Well B24. The formulae in (a) represent the mudlog correction (f_x + intercept). Further details about the reference TG model and applied magnitude corrections see Chapter 7.1.

A.3 Ties between seismic wave propagation and depth

The available seismic cube of the western Nile Delta Plio-/Pleistocene stratigraphy is referenced to the raw two-way travel time of compressional elastic waves (also known as P-waves: primary or pressure waves) that were shot and detected during the seismic surveys. Conversion of traveltime into logger's depth and *vice versa* is commonly performed using so called seismic check shots (also known as *borehole seismic* or *seismic well shots*) that are measured by "the time taken for a wave from a surface source to reach a downhole geophone anchored at a certain depth in the formation determined by the cable length" (Serra 1986, p.546).

Propagation velocity of seismic waves depends on density and elasticity of the medium (*e.g.* Milsom 2003), *i.e.* wave propagation becomes more efficient with increasing burial depth because clastic sediments lose porosity and gain stiffness during diagenesis. As sea water has a porosity of 100% the seismic wave propagation (or speed of sound) depends on pressure (or water depth; 1 m/s ~ 60 m), temperature (1 m/s ~ 0.25 °C), and salinity (1 m/s ~ 1 ‰; Mackenzie 1981, Wong & Zhu 1995).

A general survey on the checkshot quality was performed by comparison of the two-way travel time (TWT) that was measured at the sea bottom of each well location with a modelled TWT that is a function of measured water depth, average sea water column temperature (~14.9 °C from Poisson *et al.* 1981, and Mastalerz *et al.* 2007), and salinity (38.8 ‰ from Poisson *et al.* 1981) after the empirical equation of Mackenzie (1981). The modelled values are in good agreement mit the measurements (Fig. A–10).

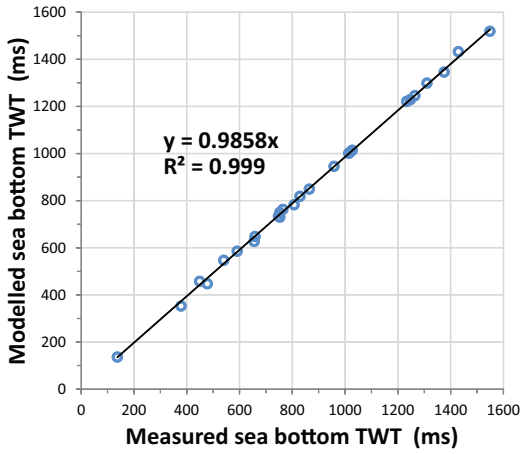

Figure A–10 Quality control on seismic sea bottom reflection (see text for details; boreholes undistinguished).

More general limitations to the accuracy of check shot information may be bias from reflection and noise effects from locally disturbed borehole walls, inclination of the well trajectory, or strong contrasts in the formation properties such as pressure compartmentalisations, tectonically induced compaction disequilibria, and phase contacts within the pore network (*e.g.* Serra 1986). However, as most of the Nile Delta wells are vertical to subvertical (max. 5° deviation; higher inclinations for B3 and B14) and burial rates were quite consistent during the Plio-/Pleistocene deposition (see Chapter 1) the burial depth *vs.* burial TWT can be approximated with power law-type regressions that have cor-

relation coefficients between 0.9993 and 1. TWT-to-depth relations with and without sea water column are plotted in Figure A–11.

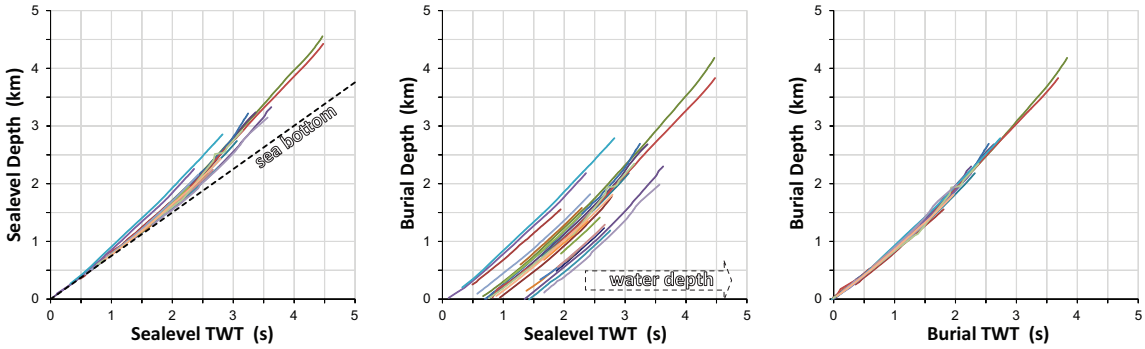

Figure A–11 Relationships between logger's depth and check shot two-way traveltime (TWT) referenced to sealevel and/or sea bottom (boreholes undistinguished but randomly colour-coded).

Given the restricted resolution of seismic data (~10m for the available Nile Delta cube) the accuracy of the quality control (Fig. A–10) and regressions obtained from Figure A–11c will suffice to seismic correlate marker horizons and accumulations with the information derived from conventional wireline logs (Part III) as well as the core lithofacies (Part II) and gas analytical results (Part I) that were synchronised with the logger's depth (Appendix A.1 and A.2).

Appendix B: Supplementary Material

This chapter contains information that has either secondary significance for the migration analysis (Appendix B.1) or illustrates previously mentioned workflows and interpretations that were unsuitable for incorporation into the main thesis body for volumetric reasons (Appendices B.2 and B.3).

B.1 Mudrock characterisation

In addition to the pore- and grain-size measurements (Chapter 4) that were used to calibrate the CI model (Chapter 5), laboratory experiments have been conducted to determine the grain density as well as carbon and sulphur content of the 92 provided core samples.

For general sample preparation, a minimum of 3 grams of sample fragments were ground with a mortar to achieve a resulting grain size of less than 500 µm, which was validated by sieving. 2.65 ± 0.15 g of each sample powder were isolated for grain density analysis, while the remaining 0.35 ± 0.15 g was saved for TOC, TC and TS measurements in separate vials.

Methodology: Grain density A subset of 7 powder samples at a time was isolated in density bottles of known weight, and then dried in the oven (at least 100°C) for about 24 hours (overnight). Before use, the density bottles were already oven dried and stored in a desiccator to prevent them from picking up moisture. Ground quartz (G_s = 2.65 ± 0.02 g/cm^3) was taken as a standard, completing each sample subset via an 8th density bottle.

Figure B–1 Bottled grain density sample.

After oven drying, the sample bearing bottles were gently cooled down within a desiccator and their weight noted. The rock powder then was wetted by up to half-filling and thoroughly swirling the bottles with deionised, air-drained water. Meanwhile appended air bubbles were removed by leaving the muddy samples for an hour in the vacuum desiccator. Then the bottles were filled to the very top with the treated water (Fig. B–1) and placed into a water bath at a temperature of exactly 25°C, which is common standard for density measurements. After at least 1 hour, the corresponding lids were put into the flasks, and after reassurance was gained that the lids' channels became flushed up to

the top and no air bubbles were trapped, the flasks were subsequently taken out of the bath, dried and weighed. Then the flasks were cleaned thoroughly and put into the oven (>100°C) to be ready for the next set of samples.

Finally, grain density G_S was calculated as a function of the measured weights and the known weight of each bottle filled with deionised water. The formula is as follows:

$$G_S\ [g/cm^3] = (m_{b+s} - m_b) / (m_{b+s} + m_{b+w} - m_b - m_{b+s+w}) \qquad \textit{(Ba)}$$

with mass weight *m* and the subscripts *b* for bottle, *s* for sample and *w* for water, respectively. The average deviation of the resulting grain densities from the quartz standard was 0.43%.

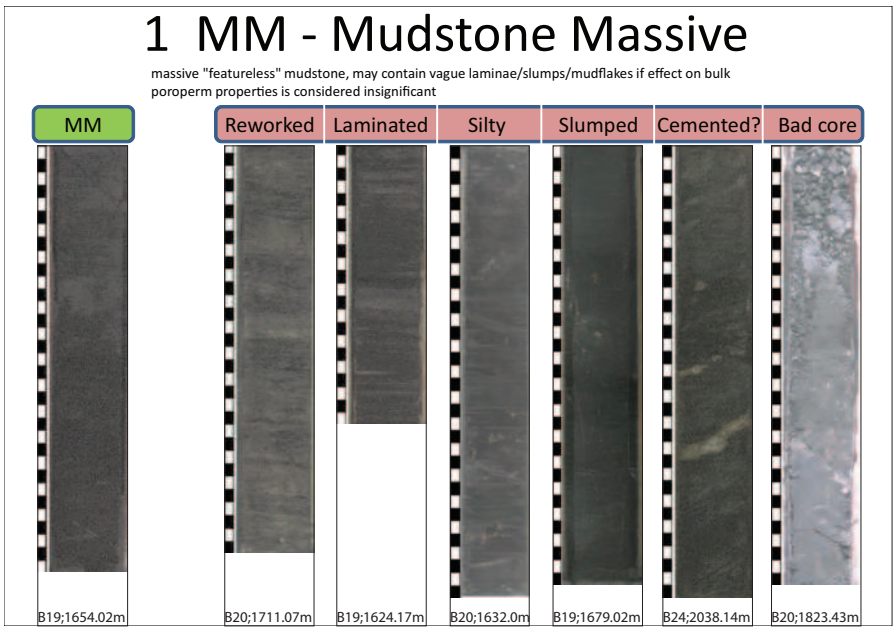
Methodology: Organic Carbon Approximately 0.1 ± 0.002 g of sample material, each in a porous crucible, was treated with a minimum of 1 mL 4.0 mol/L hydrochloric acid (in the well of a fume cupboard) to remove inorganic carbon (carbonates). After the acid has drained from the crucibles (4-8 hours) the sample array (similar to Fig. B–2a) was dried at 65°C for 16-24 hours.

Measurement of the residual organic carbon fraction was conducted by quantitative infrared detection of the carbon dioxide that was released during sample combustion in a stream of oxygen (Fig. B–2b). The utilised LECO CS244 CarbonSulphur Analyser has been calibrated prior to each batch (~ 30 samples) with a minimum of 5 standard steel rings of certified carbon content. A scoopful of both iron chips (Sci-Lab part no. SL266) and tungsten (SciLab part no. AR077) served as accelerators for the sample combustion process (see loaded crucibles in Fig. B–2a). To prevent contamination of the samples, the crucible tray was covered with aluminium foil until the samples were analysed.

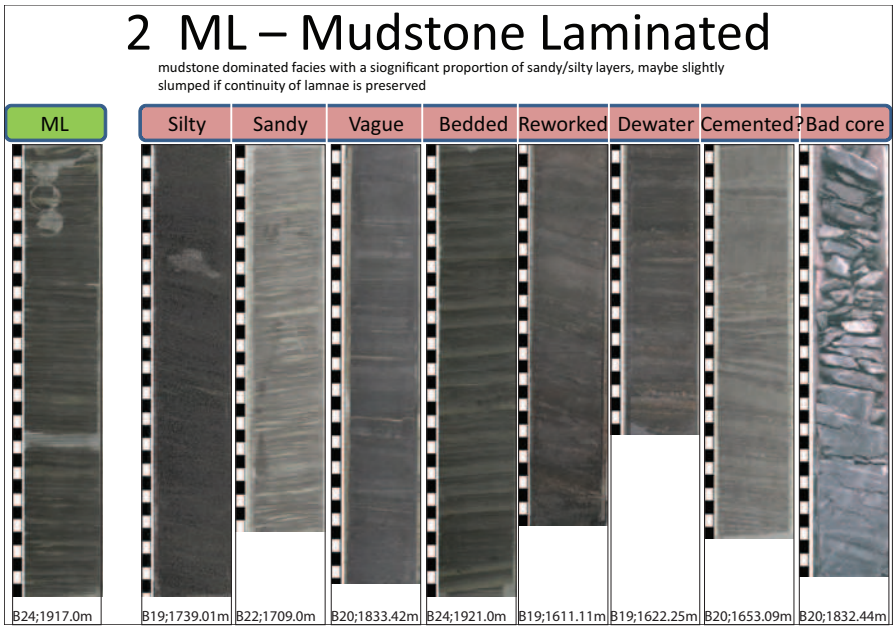
Figure B–2 (a) TOC samples with metal accelerator prior to measurement and (b) glowing crucible after combustion.

One out of 10 samples was measured twice, with the result that an average deviation of 1.42% validates the repeatability of the method. The average deviation from the stand-

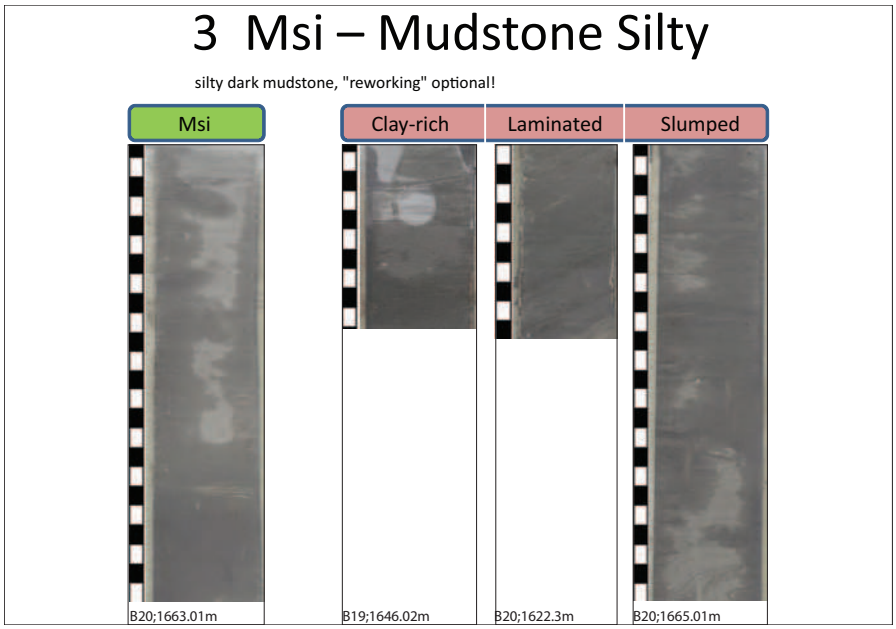
ard was 2.18%, and measurement of blank crucibles met the detection limit of 0.02%.



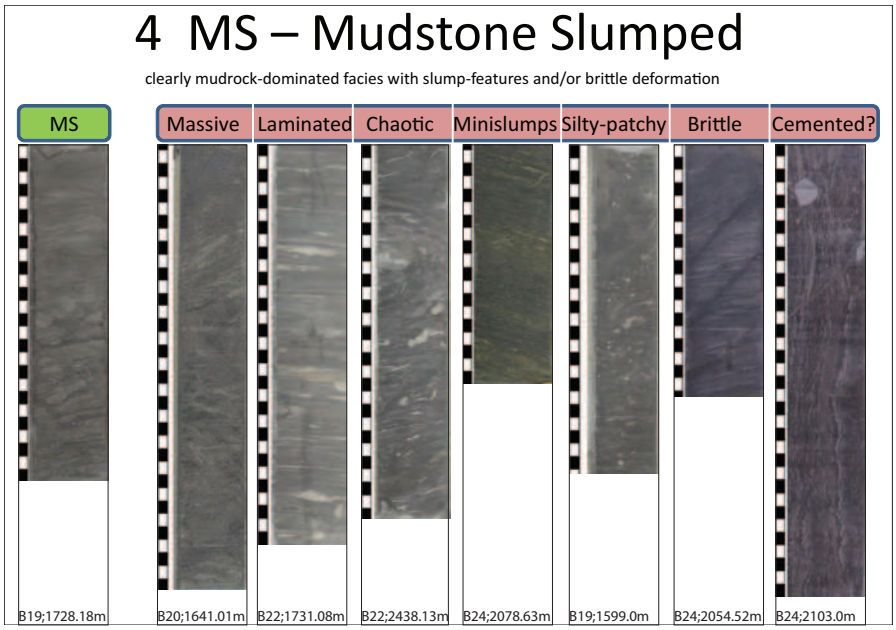
Methodology: Total Carbon and Sulphur The analysis of total carbon (TC) and total sulphur (TS) follows a methodology which is similar to the TOC analysis as described above. The only difference is in sample treatment prior to combustion: carbonates are being preserved by dismissing the treatment with hydrochloric acid, and accordingly non-porous crucibles may be utilised.



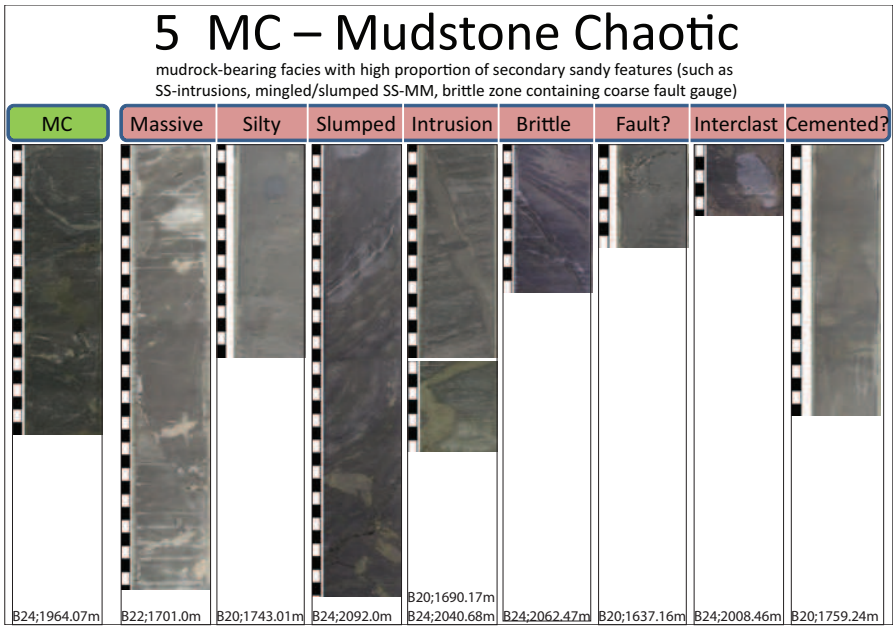
Mean deviation of the measured standards is 0.27% for TC and 0.38% for TS, respectively, and blank crucibles showed values below detection limit. Substraction of TOC from TC gives the percentage of total inorganic carbon (TIC) for each sample.



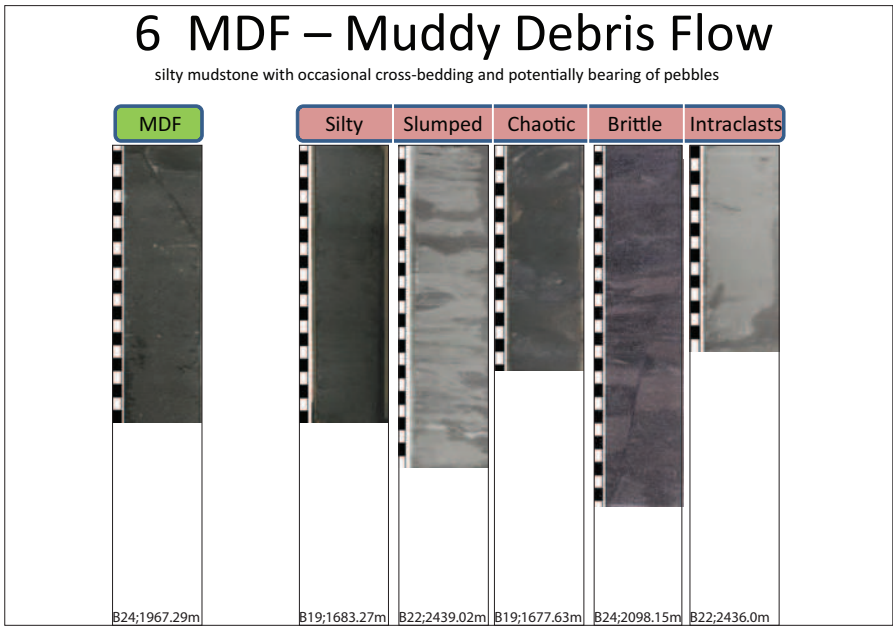
Complete Mudrock Database The results from the laboratory analysis of the 92 mudrock core samples have been summarised in Appendix C.

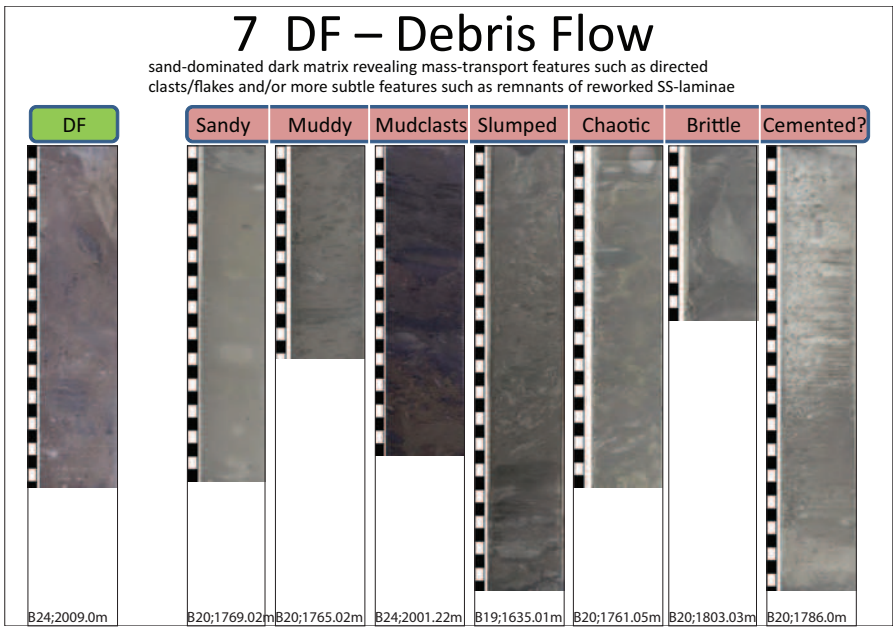


B.2 Borderline decisions in lithofacies interpretation



Variances in the original lithofacies typology from Chapter 5 (Figure 5–3) are illustrated in the following pages. The arrangement of core photographs show model examples next to selected borderline cases that are representative for the priority wells B19, B20, B22, and B24 (see Figs. 1–3 and 1–4a for geographical locations). Marginal scale bars (black and white block alternations) are on the order of 2cm per unit. Photographs represent raw (original) BP data prior to digital removal of artificial artefacts. Well provenance and top original (un-shifted) core depth (from Kelly Bushing) are indicated below each sample.





2 ML – Mudstone Laminated
mudstone dominated facies with a siognificant proportion of sandy/silty layers, maybe slightly slumped if continuity of lamnae is preserved
ML
Silty
Sandy
Vague
Bedded
Reworked
Dewater
Cemented?
Bad core
